

NOTES ON THE RIEMANN HYPOTHESIS

RICARDO PÉREZ MARCO

ABSTRACT. Our aim is to give an introduction to the Riemann Hypothesis and a panoramic view of the world of zeta and L -functions. We first review Riemann's foundational article and discuss the mathematical background of the time and his possible motivations for making his famous conjecture. We discuss the most relevant developments after Riemann that have contributed to a better understanding of the conjecture.

1. EULER TRANSALGEBRAIC WORLD.

The first non-trivial occurrence of the real zeta function

$$\zeta(s) = \sum_{n=1}^{\infty} n^{-s}, \quad s \in \mathbb{R}, \quad s > 1,$$

appears to be in 1735 when Euler computed the infinite sum of the inverse of squares, the so called “Basel Problem”, a problem originally raised by P. Mengoli and studied by Jacob Bernoulli,

$$\zeta(2) = \sum_{n=1}^{\infty} n^{-2}.$$

Euler's solution was based on the *transalgebraic* interpretation of $\zeta(2)$ as the Newton sum of exponent s , for $s = 2$, of the transcendental function $\frac{\sin \pi z}{\pi z}$, which vanishes at each non-zero integer. As Euler would write:

$$\frac{\sin \pi z}{\pi z} = \prod_{n \in \mathbb{Z}^*} \left(1 - \frac{z}{n}\right).$$

Or, more precisely, regrouping the product for proper convergence (in such a way that respects an underlying symmetry, here $z \mapsto -z$, which is a recurrent important idea),

$$\begin{aligned} \frac{\sin \pi z}{\pi z} &= (1 - z)(1 + z) \left(1 - \frac{z}{2}\right) \left(1 + \frac{z}{2}\right) \dots = \prod_{n=1}^{\infty} \left(1 - \frac{z^2}{n^2}\right) \\ &= 1 - \left(\sum_{n=1}^{\infty} \frac{1}{n^2}\right) z^2 + \left(\sum_{n,m=1}^{\infty} \frac{1}{n^2 m^2}\right) z^4 + \dots \end{aligned}$$

On the other hand, the power series expansion of the sine function gives

$$\begin{aligned}\frac{\sin \pi z}{\pi z} &= \frac{1}{\pi z} \left(\pi z - \frac{1}{3!}(\pi z)^3 + \frac{1}{5!}(\pi z)^5 - \dots \right) \\ &= 1 - \frac{\pi^2}{6} z^2 + \frac{\pi^4}{120} z^4 - \dots,\end{aligned}$$

and identifying coefficients, we get

$$\zeta(2) = \frac{\pi^2}{6} .$$

In the same way, one obtains

$$\zeta(4) = \frac{\pi^4}{90} ,$$

as well as the values $\zeta(2k)$ for each positive integer value of k . This seems to be one of the first occurrences of symmetric functions in an infinite number of variables, something that is at the heart of Transalgebraic Number Theory.

This splendid argument depends crucially on the fact that the only zeros of $\sin(\pi z)$ in the complex plane are on the real line, and therefore are reduced to the natural integers. This, at the time, was the central point for a serious objection: It was necessary to prove the non-existence of non-real zeros of $\sin(\pi z)$. This follows easily from the unveiling of the relationship of trigonometric functions with the complex exponential (due to Euler) or to Euler Γ -function via the complement (or reflection) formula (due to Euler). Thus, we already meet at this early stage the importance of establishing that the divisor of a transcendental function lies on a line. We highlight this notion:

Divisor on lines property (DL). *A meromorphic function on the complex plane has its divisor on lines, or has the **DL** property, if its divisor is contained in a finite number of horizontal and vertical lines.*

Meromorphic functions satisfying the **DL** property do form a multiplicative group. The **DL** property is close to having an order two symmetry or satisfying a functional equation. More precisely, a meromorphic function of finite order satisfying the **DL** property with its divisor contained in a single line, after multiplication by the exponential of a polynomial, does satisfy a functional equation that corresponds to the symmetry with respect to the divisor line. Obviously the converse is false. In our example the symmetry discussed comes from real analyticity.

Another transcendental function, also well known to Euler, satisfying the **DL** property, is Euler gamma function,

$$\Gamma(s) = \lim_{n \rightarrow \infty} \frac{n^n n!}{s(s+1) \cdots (s+n)} .$$

It interpolates the factorial function and has its divisor, consisting only of poles, at the non-positive integers. Again, real analyticity gives one functional equation. The zeta function $\zeta(s)$ is exactly Newton sum of power s for the zeros of the entire

function Γ^{-1} , which is given by its Weierstrass product (where $\gamma = 0.5772157\dots$ is Euler constant)

$$\frac{1}{\Gamma(s)} = se^{\gamma s} \prod_{n=1}^{+\infty} \left(1 + \frac{s}{n}\right) e^{-s/n}.$$

The Γ -function decomposes in the **DL** group our previous sine function by the complement formula

$$\frac{\sin \pi z}{\pi z} = \frac{1}{\Gamma(1+z)} \cdot \frac{1}{\Gamma(1-z)}.$$

This “interpolation idea” which is at the origin of the definition of the Γ -function permeates the work of Euler and is also central in the ideas of Ramanujan, who independently obtained most of these classical results. Interpolation is very important also for the theory of zeta functions. Although for the solution of the Basel problem only one value at $s = 2$ (Newton sum of squares) does matter, the interpolation to the real and the complex of the Newton sums, looking at the exponent as parameter, is a fruitful *transalgebraic* idea. Obviously the function $\zeta(2s)$ is the interpolation of the Newton sums of the roots of the $\frac{\sin(\pi\sqrt{z})}{\pi\sqrt{z}}$ transcendental function. Holomorphic functions of low order and with symmetries are uniquely determined by its values on arithmetic sequences of points as follows from Weierstrass theory of entire functions. Remarkably, under convexity assumptions, this also holds in the real domain (for example Bohr-Mollerup characterization of the Γ -function). It is precisely this point of view and the interpolation from the same points (real even integers) that leads to the p -adic version of the zeta function by Kubota and Leopold (see section 4.10).

There is another key point in Euler’s argument. Multiplying

$$s(z) = \frac{\sin \sqrt{z}}{\sqrt{z}} = 1 - \frac{1}{3!}z + \frac{1}{5!}z^2 + \dots$$

by the exponential of an entire function changes the coefficients of the power series expansion at 0, but not its divisor. We can keep these coefficients rational and the entire function of finite order by multiplication by the exponential of a polynomial with rational coefficients. Therefore we cannot expect that direct Newton relations hold for the roots an arbitrary entire function. But we know that this is true for entire functions of order < 1 which can be treated as polynomials, as is the case for $s(z)$. Euler’s transalgebraic point of view also “proves” the result: $s(z)$ behaves as the minimal entire function for the transalgebraic number π^2 , similar to the minimal polynomial of an algebraic number in Algebraic Number Theory. Although this notion is not properly defined in a general context of entire function with rational coefficients, the idea is that it is the “simplest” (in an undetermined sense, but meaning at least of minimal order) entire function with rational coefficients having π^2 as root. Note here a major difference between even and odd powers of π , which is the origin of the radical computability difference of $\zeta(2n)$ and $\zeta(2n+1)$. This creative ambiguity between algebraic and transalgebraic permeates Euler’s work as well as in some of his most brilliant successors like

Cauchy and most notably Galois in his famous memoir on resolution of algebraic (transalgebraic?) equations [19]. Only the transalgebraic aspects of Galois memoir can explain the failure of Poisson to understand some basic facts, and can explain some notations and claims, in particular of the lemma after the main theorem where Galois mentions the case of “infinite number of roots”.

Transalgebraicity is an extremely powerful “philosophical” principle that some mathematicians of the XIXth century seem to be well aware of. In general terms we would say that *analytically unsound manipulations provide correct answers when they have an underlying transalgebraic background*. This deserves to be vaguely stated as a general guiding principle:

Transalgebraic Principle (TP). *Divergent or analytically unsound algebraic manipulations yield correct results when they have a transalgebraic meaning.*

We illustrate this principle with one of Euler’s most famous examples. The transalgebraic meaning of the exponential comes from Euler’s classical formula:

$$e^z = \lim_{n \rightarrow +\infty} \left(1 + \frac{z}{n}\right)^n .$$

From Euler’s viewpoint the exponential function is nothing else but a “polynomial” with a single zero of infinite order at infinity. Thus we can symbolically write:

$$e^z = \left(1 + \frac{z}{\infty}\right)^{+\infty} ,$$

noting that both infinities in the formula are distinct in nature: ∞ is a geometric point on the Riemann sphere (the zero) and $+\infty$ is the infinite number (the order).

Then we can recover the main property of the exponential by invoking to the Transalgebraic Principle and the following computation (using $\infty^{-2} \ll \infty^{-1}$)

$$\begin{aligned} e^z . e^w &= \left(1 + \frac{z}{\infty}\right)^{+\infty} . \left(1 + \frac{w}{\infty}\right)^{+\infty} \\ &= \left(1 + \frac{z+w}{\infty} + \frac{z.w}{\infty^2}\right)^{+\infty} \\ &= \left(1 + \frac{z+w}{\infty}\right)^{+\infty} \\ &= e^{z+w} . \end{aligned}$$

The next major appearance of the zeta function was in 1748, when Euler obtained his celebrated *product formula*, which is equivalent to the Fundamental

Theorem of Arithmetic, as we see from the key manipulation,

$$\begin{aligned}\zeta(s) &= \sum_{n=1}^{\infty} n^{-s} = \sum_{p_1, p_2, \dots, p_r} (p_1 \dots p_r)^{-s} \\ &= \prod_p (1 + p^{-s} + p^{-2s} + \dots) \\ &= \prod_p (1 - p^{-s})^{-1},\end{aligned}$$

where $p = 2, 3, 5, 7, 11, \dots$ runs over all prime numbers. The product formula provides the link between the zeta function and prime numbers. Or, if we prefer, once we consider the extension of Riemann zeta function to the complex plane, first proposed by Riemann, between prime numbers and complex analysis. The meromorphic extension of the zeta function to the complex plane, first proved by Riemann, is one of the main contributions to the theory and the reason why the name of Riemann is attached to the zeta function. Observe that complexification comes naturally once we realize that each local factor

$$\zeta_p(s) = (1 - p^{-s})^{-1}$$

has the **DL** property, since its divisor consists only of poles located at the purely imaginary axes $i\omega_p^{-1}\mathbb{Z}$, where

$$\omega_p = \frac{\log p}{2\pi},$$

is the fundamental frequency associated to the prime p . Up to a proper complex linear rescaling (depending on p) and an exponential factor (which does not change the divisor), the local factor ζ_p^{-1} is nothing but the sine function studied before:

$$\zeta_p(s)^{-1} = 1 - p^{-s} = 2ip^{s/2} \sin(\pi\omega_p(-is)).$$

Observe also that from the very definition of prime number it follows that the frequencies $(\omega_p)_p$ are \mathbb{Q} -independent.

Already at this early stage, since the **DL** property is invariant by finite products, it seems natural to conjecture that the zeta function does also satisfy the **DL** property. We do not mean that the **DL** property should be invariant by infinite products in general. According to the Transalgebraic Principle **TP**, it is natural to conjecture this for *Euler products* of arithmetical nature. There is little support, at this stage, for this conjecture. Later on more evidence will appear. Due to the complete lack of arguments in the literature in support for the Riemann Hypothesis, this weaker and related conjecture is worth mentioning for its appealing nature, and may well be one of the original motivations of B. Riemann for conjecturing the Riemann Hypothesis. We can formulate it in the following imprecise form:

Conjecture. *The **DL** property is invariant by arithmetical Euler products.*

This conjecture fits well from what we actually know of the scope of the Riemann Hypothesis: We only expect the Riemann hypothesis to hold when an Eulerian factorization exists. The reason is the Davenport-Heilbronn zeta function for which

the Riemann Hypothesis fails, although it shares many properties with Riemann zeta function (see [28] section 3).

From the product formula, Euler derived a new analytic proof and strengthened Euclid's result on the infinity of prime numbers. We only need to work with the real zeta function. For real $s > 1$ the product formula shows that $\zeta(s)$ remains positive, thus we can take its logarithm and compute by absolute convergence

$$\log \zeta(s) = \sum_p -\log(1 - p^{-s}) = \sum_p \sum_{n=1}^{\infty} \frac{p^{-ns}}{n} = \left(\sum_p p^{-s} \right) + \sum_{n=2}^{\infty} \frac{1}{n} \left(\sum_p p^{-ns} \right)$$

Let $\mathcal{P}(s) = \sum_p p^{-s}$ be the first series in the previous formula and $R(s)$ the remainder terms. Since $R(s)$ converges for $s > \frac{1}{2}$, and is uniformly bounded in a neighborhood of 1, the divergence of the harmonic series $\zeta(1) = \lim_{s \rightarrow 1^+} \zeta(s) = \sum_{n=1}^{+\infty} \frac{1}{n}$ is equivalent to that of

$$\mathcal{P}(1) = \sum_p \frac{1}{p} = \infty .$$

Thus, there are infinitely many prime numbers with a certain density, more precisely, enough to make divergent the sum of their inverses, as Euler writes:

$$\frac{1}{1} + \frac{1}{2} + \frac{1}{3} + \frac{1}{5} + \frac{1}{7} + \frac{1}{11} + \dots = +\infty .$$

Note that Euler includes 1 as prime number.

2. RIEMANN'S ARTICLE.

As we have observed, complexification not only arises naturally from Euler's work, but it is also necessary to justify his results. Euler's successful complexification of the exponential function proves that he was well aware of this fact. But the systematic study and finer properties of the zeta function in the complex domain appears first in Riemann's memoir on the distribution of prime numbers [46]. Before Riemann, P.L. Tchebycheff [51] used the real zeta function to prove rigorous bounds on the *Law of prime numbers*, conjectured by Legendre (and refined by Gauss): When $x \rightarrow +\infty$

$$\pi(x) = \#\{p \text{ prime} ; p \leq x\} \approx \frac{x}{\log x} .$$

Riemann fully exploits the meromorphic character of the extension of the zeta function to the complex plane in order to give an explicit formula for $\pi(x)$. We review in this section his foundational article [46] that contains ideas and results that go well beyond the law of prime numbers.

2.1. Meromorphic extension. Riemann starts by proving the meromorphic extension of the ζ -function from an integral formula. From the definition of Euler Γ -function (we refer to the appendix for basic facts), for real $s > 1$ we have

$$\Gamma(s) \frac{1}{n^s} = \int_0^{+\infty} e^{-nx} x^s \frac{dx}{x} .$$

From this Riemann derives

$$\Gamma(s)\zeta(s) = \int_0^{+\infty} \left(\sum_{n=1}^{+\infty} e^{-nx} \right) x^s \frac{dx}{x} = \int_0^{+\infty} \frac{e^{-x}}{1 - e^{-x}} x^s \frac{dx}{x} = I(s),$$

where the exchange of the integral and the series is justified by the local integrability of the function $x \mapsto \frac{x^{s-1}}{e^x - 1}$ at zero. Therefore

$$\zeta(s) = \frac{1}{\Gamma(s)} \int_0^{+\infty} \frac{1}{e^x - 1} x^s \frac{dx}{x} = \frac{1}{\Gamma(s)} I(s).$$

In order to prove the meromorphic extension of ζ to the whole complex plane, Riemann observes that we can transform the above integral $I(s)$ into a Hankel type contour integral for which the integration makes sense for all $s \in \mathbb{C}$. For $z \in \mathbb{C} - \mathbb{R}_+$, and $s \in \mathbb{C}$, we consider the branch $(-z)^s = e^{s \log(-z)}$ where the usual principal branch of \log in $\mathbb{C} - \mathbb{R}_-$ is taken.

FIGURE 1. Integration paths.

Let C be a positively oriented curve as in Figure 1 uniformly away from the singularities $2\pi i\mathbb{Z}$ of the integrand, for example $d(C, 2\pi i\mathbb{Z}) > 1$, with $\Re z \rightarrow +\infty$ at the ends of C , separating 0 from $2\pi i\mathbb{Z}^*$, and with 0 winding number for any singularity $2\pi ik$, with $k \neq 0$. Then the integral

$$I_0(s) = \int_C \frac{(-z)^s}{e^z - 1} \frac{dz}{z}$$

defines an entire function which, by Cauchy formula, does not depend on the choice of the path C in the prescribed class: Given another such path C' , we check that both integrals coincide by closing up both paths in increasingly larger parts of C and C' .

Now, for real $s > 1$ and $\epsilon > 0$ we can also deform the contour to obtain the expression

$$I_0(s) = - \int_{\mathbb{R}_+ + i\epsilon} \frac{(-z)^s}{e^z - 1} \frac{dz}{z} + \int_{|z|=\epsilon} \frac{(-z)^s}{e^z - 1} \frac{dz}{z} + \int_{\mathbb{R}_+ - i\epsilon} \frac{(-z)^s}{e^z - 1} \frac{dz}{z},$$

which in the limit $\epsilon \rightarrow 0$ yields

$$I_0(s) = (e^{i\pi s} - e^{-i\pi s})I(s) = 2i \sin(\pi s)I(s),$$

where we have used that the middle integral tends to zero when $\epsilon \rightarrow 0$, because $s > 1$ and for $z \rightarrow 0$

$$\frac{(-z)^s}{e^z - 1} = \mathcal{O}(|z|^{s-1}).$$

Therefore, using the complement formula for the Γ -function,

$$\zeta(s) = \frac{1}{2i \sin(\pi s)\Gamma(s)} \int_C \frac{(-z)^s}{e^z - 1} \frac{dz}{z} = \frac{\Gamma(1-s)}{2\pi i} \int_C \frac{(-z)^s}{e^z - 1} \frac{dz}{z}.$$

This identity has been established for real values of $s > 1$, but remains valid by analytic continuation for all complex values $s \in \mathbb{C}$. It results that ζ has a meromorphic extension to all of \mathbb{C} and its possible poles are located at $s = 1, 2, 3, \dots$. But from the definition for real values we know that ζ is positive and real analytic for real $s > 1$, and becomes infinity at $s = 1$, thus only $s = 1$ is a pole. We can also see directly from the formula that $s = 2, 3, \dots$ are not poles since the above integral is zero when $s \geq 2$ is an integer (Hint: Observe that $(-z)^s$ has no monodromy around 0 when s is an integer, then use Cauchy formula.) With the same argument, we get that $s = 1$ is a pole with residue $\text{Res}_{s=1}\zeta(s) = 1$, since the residue of $\Gamma(1-s)$ at $s = 1$ is -1 and by Cauchy formula

$$I_0(1) = \int_C \frac{-z}{e^z - 1} \frac{dz}{z} = -2\pi i.$$

We conclude that $\zeta(s)$ is a meromorphic function with a simple pole at $s = 1$ with residue 1.

It also follows from the integral formula that Riemann ζ function is a meromorphic function of order 1, since the Γ -function is so and the integrand has the proper growth at infinity.

2.2. Value at negative integers. To calculate the value of ζ at negative integers we introduce the Bernoulli numbers as the coefficients B_n of the power series expansion

$$\frac{z}{e^z - 1} = \sum_{n=0}^{+\infty} \frac{B_n}{n!} z^n.$$

Then we have $B_0 = 1$, $B_1 = 1$ and $B_{2n+1} = 0$ for $n \geq 1$. The first values of Bernoulli numbers are

$$B_2 = \frac{1}{6}, \quad B_4 = -\frac{1}{30}, \quad B_6 = \frac{1}{42}, \quad B_8 = -\frac{1}{30}, \quad B_{10} = \frac{5}{66}, \quad B_{12} = -\frac{691}{2730}.$$

As is often remarked, the appearance of the *sexy* prime number 691 reveals the hidden presence of Bernoulli numbers. Making use of the above development, we can write

$$\begin{aligned}\zeta(1-n) &= \frac{\Gamma(n)}{2\pi i} \int_C \left(\sum_{k=0}^{+\infty} \frac{B_k}{k!} z^k \right) (-z)^{1-n} \frac{dz}{z^2} \\ &= (-1)^{1-n} \frac{(n-1)!}{2\pi i} \sum_{k=0}^{+\infty} \frac{B_k}{k!} \int_C z^{k-n-1} dz \\ &= (-1)^{1-n} \frac{B_n}{n} .\end{aligned}$$

Thus $\zeta(1-n) = 0$ for odd $n \geq 3$, and for n even we have

$$\zeta(1-n) = -\frac{B_n}{n} \in \mathbb{Q} .$$

In particular

$$\zeta(0) = -\frac{1}{2}, \quad \zeta(-1) = -\frac{1}{12}, \quad \zeta(-3) = \frac{1}{120}, \quad \zeta(-5) = -\frac{1}{252}, \quad \zeta(-7) = \frac{1}{240},$$

and $\zeta(-2k) = 0$ for $k \geq 1$. These are referred in the literature as the *trivial zeros* of ζ . Note that these trivial zeros all lie on the real line and are compatible with the possible **DL** property for the ζ function.

2.3. First proof of the functional equation. After establishing the meromorphic extension of the zeta function, Riemann proves a functional equation for ζ that is already present in the work of Euler, at least for real integer values. He gives two proofs. The first one that we present here is a direct proof from the previous integral formula. We assume first that $\Re s < 0$.

FIGURE 2. Integration paths.

Applying the Residue Theorem to the contour integral in Figure 2, taking into account that the contribution of the outer boundary (second integral in the formula below) is zero in the limit (because $\Re s < 0$), the Residue Theorem gives (D_R is the outer circular part of the path and C_R the rest):

$$\begin{aligned} I_0(s) &= \lim_{R \rightarrow +\infty} \left(\int_{C_R} \frac{(-z)^s}{e^z - 1} \frac{dz}{z} + \int_{D_R} \frac{(-z)^s}{e^z - 1} \frac{dz}{z} \right) \\ &= -(2\pi i) \sum_{n \in \mathbb{Z}^*} \operatorname{Res}_{z=2\pi i n} \frac{(-z)^s}{e^z - 1} \frac{1}{z} \\ &= -(2\pi i) \sum_{n=1}^{+\infty} \left(\frac{(2\pi n)^s e^{-\frac{s\pi}{2}i}}{2\pi i n} + \frac{(2\pi i n)^s e^{\frac{s\pi}{2}i}}{-2\pi i n} \right) \\ &= (2\pi)^s 2i \sin\left(\frac{s\pi}{2}\right) \zeta(1-s) . \end{aligned}$$

Then $\zeta(s) = \frac{\Gamma(1-s)}{2\pi i} I_0(s)$ satisfies the functional equation,

$$(2.1) \quad \zeta(s) = 2^s \pi^{s-1} \sin\left(\frac{\pi s}{2}\right) \Gamma(1-s) \zeta(1-s) .$$

As an application, we can compute the values of ζ at even positive integers. For $s = 1 - 2n$, the functional equation gives

$$\zeta(2n) = (-1)^{n+1} \frac{2^{2n-1} B_{2n}}{(2n)!} \pi^{2n} ,$$

which is a rational multiple of π^{2n} .

Equation (2.1) can be written in a more symmetric form, by using the division and complement formula for the gamma function:

$$\begin{aligned} \Gamma(1-s) &= 2^{-s} \pi^{-\frac{1}{2}} \Gamma\left(\frac{1}{2} - \frac{s}{2}\right) \Gamma\left(1 - \frac{s}{2}\right) , \\ \sin\left(\pi \frac{s}{2}\right) &= \frac{\pi}{\Gamma\left(\frac{s}{2}\right) \Gamma\left(1 - \frac{s}{2}\right)} . \end{aligned}$$

Then:

$$\pi^{-\frac{s}{2}} \Gamma\left(\frac{s}{2}\right) \zeta(s) = \pi^{-\frac{1-s}{2}} \Gamma\left(\frac{1-s}{2}\right) \zeta(1-s) .$$

One can multiply by $s(s-1)$ in order to kill the pole at $s = 1$, respecting the symmetry, then if one introduces the extended zeta function

$$\xi(s) = \frac{1}{2} s(s-1) \pi^{-\frac{s}{2}} \Gamma(s/2) \zeta(s) ,$$

(the factor $1/2$ is only there for historical reasons because Riemann in his memoir was using the function $\Pi(s) = \Gamma(s-1)$), the functional equation becomes

$$\xi(s) = \xi(1-s) .$$

The function ξ is an entire function of order 1 whose zeros are the zeros of ζ except for the trivial ones. Since $\xi(s)$ is non-zero when $\Re s > 1$, the function does not vanish for $\Re s < 0$, so all its zeros belong to the *critical strip* $0 \leq \Re s \leq 1$. The symmetry of the equation can be formulated as the real analyticity of $\Xi(t) =$

$\xi(\frac{1}{2} + it)$, i.e. $\Xi(t) = \overline{\Xi(\bar{t})}$. Therefore we have two order two symmetries. This makes that each non-real zero ρ of ζ is associated to other zeros at the locations $1 - \rho$, $\bar{\rho}$, and $1 - \bar{\rho}$.

2.4. Second proof of the functional equation. In his memoir, Riemann gives a second proof of the functional equation that discloses an important link with modular forms. This proof plays an important role in the theory of modular L -functions (see section 4.6 and enjoy the reading of “le jardin des délices modulaires”, fourth volume of [20]). The functional equation indeed follows from the functional equation for the classical theta function.

We consider the classical θ -function

$$\theta(x) = \sum_{n \in \mathbb{Z}} e^{-n^2 \pi x^2} ,$$

and the half θ -function

$$\psi(x) = \sum_{n=1}^{+\infty} e^{-n^2 \pi x^2} ,$$

so $\theta(x) = 2\psi(x) + 1$.

Again starting from the integral formula for the Γ -function, we have

$$\pi^{-s/2} \Gamma(s/2) \frac{1}{n^s} = \int_0^{+\infty} e^{-n^2 \pi x^2} x^{\frac{s}{2}} \frac{dx}{x} ,$$

and adding up for $n = 1, 2, 3, \dots$,

$$\pi^{-s/2} \Gamma(s/2) \zeta(s) = \int_0^{+\infty} \psi(x) x^{\frac{s}{2}} \frac{dx}{x} .$$

Recall Poisson formula: For a function $f : \mathbb{R} \rightarrow \mathbb{R}$ in the rapidly decreasing Schwartz class, we have

$$\sum_{n \in \mathbb{Z}} f(n) = \sum_{n \in \mathbb{Z}} \hat{f}(n) .$$

When we apply this to the Gauss function we obtain the classical functional equation $\theta(x) = x^{-\frac{1}{2}} \theta(1/x)$ or

$$2\psi(x) + 1 = x^{-\frac{1}{2}} (2\psi(1/x) + 1) .$$

Thus, splitting the integral in two parts, integrating over $[0, 1]$ and $[1, +\infty[$, and using the functional equation $\psi(x) = x^{-1/2} \psi(1/x) + \frac{1}{2} x^{-1/2} - 1/2$ we get

$$\pi^{-s/2} \Gamma(s/2) \zeta(s) = \int_1^{+\infty} \psi(x) x^{\frac{s}{2}} \frac{dx}{x} + \int_0^1 \psi(1/x) x^{\frac{s-1}{2}} \frac{dx}{x} + \frac{1}{2} \int_0^1 (x^{\frac{s-1}{2}} - x^{\frac{s}{2}}) \frac{dx}{x} ,$$

then the change of variables $x \mapsto 1/x$ in the second integral gives the symmetric form, invariant by $s \mapsto 1 - s$,

$$\pi^{-s/2} \Gamma(s/2) \zeta(s) = -\frac{1}{s(1-s)} + \int_1^{+\infty} \psi(x) (x^{\frac{s}{2}} + x^{\frac{1-s}{2}}) \frac{dx}{x} .$$

We can also write

$$\xi(s) = \frac{1}{2} - \frac{1}{s(1-s)} \int_1^{+\infty} \psi(x) (x^{\frac{s}{2}} + x^{\frac{1-s}{2}}) \frac{dx}{x} .$$

Then Riemann manipulates further the integral expression and writes $s = \frac{1}{2} + it$ and

$$s(1-s) = t^2 + 1/4 ,$$

$$\Xi(t) = \xi\left(\frac{1}{2} + it\right) = \frac{1}{2} - 2(t^2 + 1/4)^{-1} \int_1^{+\infty} \psi(x) x^{-3/4} \cos\left(\frac{1}{2}t \log x\right) dx ,$$

which gives, by integration by parts (and using the functional equation for ψ),

$$(2.2) \quad \Xi(t) = 4 \int_1^{+\infty} \frac{d(x^{-3/2}\psi(x))}{dx} x^{-1/4} \cos\left(\frac{1}{4}t \log x\right) dx .$$

2.5. The Riemann Hypothesis. At that point of his memoir, Riemann observes that formula (2.2) shows that the function Ξ can be expanded in a rapidly convergent power series of t^2 . Then he makes the observation that the only zeros are in the strip $-i/2 \leq \Im t \leq i/2$. Moreover he estimates the number of zeros of Ξ with real part in $[0, T]$ explaining how to obtain the result by a contour integration and giving the asymptotic (Riemann–Von Mangoldt)

$$N(T) \approx \frac{T}{2\pi} \log \frac{T}{2\pi} - \frac{T}{2\pi} .$$

Then he continues making a curious observation:

One now finds indeed approximately this number of real roots within these limits, and it is very likely that all roots are real.

Certainly, one would wish to have a rigorous proof of this proposition; but I have meanwhile temporarily left this question after some quick futile attempts, as it appears unnecessary for the immediate purpose of my investigations.

In the manuscript notes that he left, one can find the numerical computation of some of the first zeros (recall that γ is a zero of Ξ if and only if $\rho = 1/2 + i\gamma$ is a zero of ξ),

$$\begin{aligned} \gamma_1 &= 14.134725\dots, \\ \gamma_2 &= 21.022039\dots, \\ \gamma_3 &= 25.01085\dots, \\ \gamma_4 &= 30.42487\dots, \\ &\vdots \end{aligned}$$

We refer to non-real zeros of ζ as *Riemann zeros*. The first part on Riemann's quotation seems to not have been properly appreciated: He claims to know that there are an infinite number of zeros for ζ in the critical line, and that if $N_0(T)$ is

the number of zeros on the critical line with imaginary part in $[0, T]$, then when $T \rightarrow +\infty$

$$N_0(T) \approx \frac{T}{2\pi} \log \frac{T}{2\pi} - \frac{T}{2\pi} .$$

Only in 1914 G. H. Hardy proved that $N_0(T) \rightarrow +\infty$ when $T \rightarrow +\infty$, i.e. that there are an infinite number of zeros on the critical line. Hardy actually got the estimate, $C > 0$ universal constant

$$N_0(T) > C T ,$$

which was improved in 1942 by A. Selberg to

$$N_0(T) > C T \log T ,$$

and later by N. Levinson (1974) to get an explicit 1/3 proportion of zeros (and J.B. Conrey (1989) got 2/5), but so far Riemann's claim that $N_0(T) \approx N(T)$ remains an open question.

The second part in Riemann quotation attracted worldwide attention. He indicates that it is very likely that $N_0(T) = N(T)$ or in other terms, he is formulating what we now call the Riemann Hypothesis:

Riemann Hypothesis. *Non-real zeros of the Riemann zeta function ζ are located in the critical line $\Re s = \frac{1}{2}$.*

Apart from his numerical study, we may ask what might be Riemann's intuition behind such claim. Obviously we can only speculate about this. As we see next, there seems to be some transalgebraic philosophical support, which may well be the motivation behind his intuition.

We have seen that the functional equation forces the introduction of a natural complement Γ -factor with zeros in the real axis that satisfies the **DL** property (as well as the factor $s(1-s)$ which removes the pole at $s = 1$, keeping the symmetry). Thus all the natural algebra related to Riemann zeta function involves functions in the **DL** class. This indicates that the whole theory is natural in this class of functions.

The zeta function satisfies the **DL** property if its non-real zeros lie on vertical lines. These vertical lines should be symmetric with respect to $\Re s = 1/2$. The strongest form of this property is when we have a minimal location of the non-real zeros in a single vertical line, that must necessarily be the critical line by symmetry of the functional equation. This is exactly what the Riemann Hypothesis postulates. Moreover, the transalgebraic principle **TP** coupled with the evidence that all Euler factors are in the **DL** class, gives support to the conjecture.

Apparently the conjecture is called "hypothesis" because Riemann's computations show that the location of the zeros give further estimates on the error term of the formula for the Density of Prime Numbers. Each non-trivial zero gives an oscillating term whose magnitude depends on the location of each zero, and more precisely on its real part. Under the Riemann Hypothesis one can show that for any $\epsilon > 0$,

$$\pi(x) = \text{li}(x) + \mathcal{O}(x^{\frac{1}{2}+\epsilon}) ,$$

where li denotes the logarithmic integral

$$\text{li}(x) = \int_0^x \frac{dt}{\log t} = \lim_{\epsilon \rightarrow 0} \left(\int_0^{1-\epsilon} \frac{dt}{\log t} + \int_{1+\epsilon}^x \frac{dt}{\log t} \right),$$

and we have the asymptotic development, when $x \rightarrow +\infty$,

$$\text{li}(x) \approx \frac{x}{\log x} \sum_{n=0}^{+\infty} \frac{n!}{(\log x)^n} \approx \frac{x}{\log x} + \frac{x}{(\log x)^2} + \dots$$

Conversely, this estimate also implies the Riemann Hypothesis. Bounds on the error term and zero free regions in the critical strip are intimately related.

The relation between Riemann ζ -function and prime numbers is given by the Euler product, that unfortunately only holds in the half plane $\Re s > 1$. A straightforward formula linking Riemann ζ -function and the prime counting function $\pi(x)$ is (see [52] p.2), for $\Re s > 1$,

$$\log \zeta(s) = s \int_2^{+\infty} \frac{\pi(x)}{x(x^s - 1)} dx.$$

The connection with the zeros can be readily seen by computing the logarithmic derivative, for real $s > 1$

$$\log \zeta(s) = - \sum_p \log(1 - p^{-s}) = \sum_{n=1}^{+\infty} \sum_p \frac{1}{n} p^{-ns},$$

thus

$$\frac{\zeta'(s)}{\zeta(s)} = - \sum_{p,n \geq 1} \log p p^{-ns}.$$

On the other hand

$$\zeta(s) = \frac{\pi^{s/2}}{\Gamma(s/2)} \cdot \frac{2}{s(s-1)} \xi(s) = \frac{\pi^{s/2}}{\Gamma(s/2)} \cdot \frac{2}{s(s-1)} \xi(0) \prod_{\rho}^* \left(1 - \frac{s}{\rho} \right),$$

where the product extends over the non-trivial zeros pairing symmetrical ρ and $1 - \rho$ to ensure convergence. The product expansion involving the zeros is only properly justified by Weierstrass and Hadamard work on entire functions, but since Euler this type of expansions for entire functions of order 1 is familiar to analysts. Disagreeing with other authors, we have little doubt that Riemann was able to justify this point if needed. In fact he mentions the asymptotic density of zeros in order to justify the expansion and this is a key point. Computing the logarithmic derivative:

$$\frac{\zeta'(s)}{\zeta(s)} = \frac{1}{2} \log \pi - \frac{1}{2} \frac{\Gamma'(s/2)}{\Gamma(s/2)} - \frac{1}{s} - \frac{1}{s-1} + \sum_{\rho}^* \frac{1}{s-\rho},$$

and finally we get a relation that is the starting point for many results on the distribution of prime numbers:

$$(2.3) \quad \begin{aligned} \sum_{n \geq 1} \Lambda(n) n^{-s} &= \sum_{p, n \geq 1} \log p \, p^{-ns} \\ &= -\frac{1}{2} \log \pi + \frac{1}{2} \frac{\Gamma'(s/2)}{\Gamma(s/2)} + \frac{1}{s} + \frac{1}{s-1} - \sum_{\rho}^* \frac{1}{s-\rho}, \end{aligned}$$

where Λ is the Von Mangoldt function defined by $\Lambda(n) = \log p$ if $n = p^m$ or $\Lambda(n) = 0$ otherwise.

Another indication that can give some support to the Riemann Hypothesis, and that was at the origin of famous unsuccessful attempts, is the formula

$$\frac{1}{\zeta(s)} = \prod_p (1 - p^{-s}) = \sum_{n=1}^{+\infty} \frac{\mu(n)}{n^s},$$

where μ is Möbius function: As follows from the formula, $\mu(n) = 0$ if some square divides n , and $\mu(p_1 p_2 \dots p_l) = (-1)^l$, for p_1, \dots, p_l distinct.

Obviously the vanishing of μ at multiples of squares and its changing sign gives a better chance to have the series convergent for $\Re s > 1/2$, something that obviously would imply the Riemann Hypothesis. This would be equivalent to have the estimate for the Mertens function $M(x)$, for every $\epsilon > 0$,

$$M(x) = \sum_{1 \leq n \leq x} \mu(n) = \mathcal{O}(x^{1/2+\epsilon}).$$

Unfortunately, nobody has even been able to prove convergence for $\Re s > \sigma$ with $\sigma < 1$.

2.6. The Law of Prime Numbers. The goal of Riemann's article is to present a formula for the law of prime numbers. Starting from the formula, for real $s > 1$,

$$\log \zeta(s) = - \sum_p \log(1 - p^{-s}) = \sum_{p, n \geq 1} \frac{1}{n} p^{-ns},$$

he gives an integral form to the sum on the right observing that

$$p^{-ns} = s \int_{p^n}^{+\infty} \frac{dx}{x^{s+1}} = s \int_0^{+\infty} \mathbf{1}_{[p^n, +\infty)} x^{-s} \frac{dx}{x},$$

thus

$$(2.4) \quad \frac{\log \zeta(s)}{s} = \int_1^{+\infty} \Pi(x) x^{-s} \frac{dx}{x},$$

where Π is the step function

$$\Pi = \sum_{\substack{p \geq 2 \\ n \geq 1}} \frac{1}{n} \mathbf{1}_{[p^n, +\infty)}.$$

Equation (2.4) is the exact formula that Riemann writes, and, as noted in [18], this seems to indicate that Riemann, as Euler, considered the number 1 as a prime

number (but the sums on primes do start at $p = 2$). The jumps of Π are positive, located at the powers p^n of primes and have magnitude $1/n$, thus we can also write

$$\Pi(x) = \pi(x) + \frac{1}{2}\pi(x^{\frac{1}{2}}) + \frac{1}{3}\pi(x^{\frac{1}{3}}) + \dots = \sum_{n=1}^{+\infty} \frac{1}{n}\pi(x^{\frac{1}{n}}) ,$$

where as usual $\pi(x)$ is the number of primes less than or equal to x . Note that $\pi(x)$ can be recovered from $\Pi(x)$ by Möbius inversion formula:

$$\pi(x) = \sum_{n=1}^{+\infty} \frac{\mu(n)}{n}\Pi(x^{\frac{1}{n}}) = \Pi(x) - \frac{1}{2}\Pi(x^{\frac{1}{2}}) - \frac{1}{3}\Pi(x^{\frac{1}{3}}) + \frac{1}{6}\Pi(x^{\frac{1}{6}}) + \dots .$$

Now the integral in (2.4) is a Mellin transform, or a Fourier-Laplace transform in the $\log x$ variable

$$(2.5) \quad \frac{\log \zeta(s)}{s} = \int_1^{+\infty} \Pi(x) e^{-s \log x} d(\log x) ,$$

and Riemann appeals to the Fourier inversion formula to get, previous proper redefinition of Π at the jumps (as the average of left and right limit as usual in Fourier analysis), $\Pi^*(x) = (\Pi(x+0) + \Pi(x-0))/2$,

$$(2.6) \quad \Pi^*(x) = \frac{1}{2\pi i} \int_{a-i\infty}^{a+i\infty} \frac{\log \zeta(s)}{s} x^s ds ,$$

where the integration is taken on a vertical line of real part $a > 1$.

Next, taking the logarithm of the identity

$$\zeta(s) = \frac{\pi^{s/2}}{\Gamma(s/2)} \cdot \frac{2}{s(s-1)} \quad \xi(s) = \frac{\pi^{s/2}}{\Gamma(s/2)} \cdot \frac{2}{s(s-1)} \quad \xi(0) \prod_{\rho}^* \left(1 - \frac{s}{\rho}\right) ,$$

we get

$$\log \zeta(s) = \frac{s}{2} \log \pi - \log(\Gamma(s/2)) - \log(s(s-1)/2) + \log \xi(0) + \sum_{\rho}^* \log \left(1 - \frac{s}{\rho}\right) .$$

We would like to plug this expression into the inversion formula. Unfortunately there are convergence problems. Riemann uses the classical trick in Fourier analysis of making a preliminary integration by parts in order to derive from (2.6) a convenient formula where the previous expression can be plug in, and the computation carried out integrating term by term (but always pairing associated non-trivial zeros),

$$(2.7) \quad \Pi^*(x) = -\frac{1}{2\pi \log x} \int_{a-i\infty}^{a+i\infty} \frac{d}{ds} \left(\frac{\log \zeta(s)}{s} \right) x^s ds .$$

Once we replace $\log \zeta(s)$ and we compute several integrals, we get (see [18] [15] for details) the main result in Riemann's memoir:

$$\Pi^*(x) = \text{li}(x) - \sum_{\Im \rho > 0} (\text{li}(x^{\rho}) + \text{li}(x^{1-\rho})) + \int_x^{+\infty} \frac{dt}{t(t^2-1) \log t} - \log(2) ,$$

thus if the oscillating part coming from the non-trivial zeros can be neglected, the logarithmic integral

$$\operatorname{li}(x) = \int_0^x \frac{dx}{\log x}$$

gives the principal part. Note that the integral on the right side converges to 0 when $x \rightarrow +\infty$ and thus is irrelevant for the asymptotic. Note also that the series cannot be uniformly convergent since the sum is a discontinuous function. Finally, by Möbius inversion we get, denoting $\pi^*(x) = (\pi(x+0) + \pi(x-0))/2$,

$$\pi^*(x) = \sum_{n=1}^{+\infty} \frac{\mu(n)}{n} \operatorname{li}\left(x^{\frac{1}{n}}\right) + R(x),$$

where the remainder $R(x)$ is given, up to bounded terms, by the oscillating part coming from the non-trivial zeros

$$R(x) = \sum_{n=1}^{+\infty} \sum_{\rho} \frac{\mu(n)}{n} \operatorname{li}\left(x^{\frac{\rho}{n}}\right) + \mathcal{O}(1).$$

The first term in (2.6) suggest the asymptotic when $x \rightarrow +\infty$,

$$\pi(x) \approx \operatorname{li}(x) \approx \frac{x}{\log x},$$

but Riemann didn't succeed in carrying out a control of the remainder, and the result was only proved rigorously, independently, by J. Hadamard and C.J. de la Vallée Poussin in 1896 (see [24] and [53], [54]), thus settling the long standing conjecture of Legendre and Gauss. The methods of Hadamard and de la Vallée Poussin give the estimate,

$$\pi(x) = \operatorname{li}(x) + \mathcal{O}\left(xe^{-c \log x}\right),$$

where $c > 0$ is a constant. The Riemann Hypothesis would be equivalent to the much stronger estimate

$$\pi(x) = \operatorname{li}(x) + \mathcal{O}(\sqrt{x} \log x).$$

Only more than half a century later, in 1949, P. Erdős and A. Selberg succeeded in giving a proof that didn't require the use of complex analysis. But the best bounds on the error do require the use of complex variable methods.

Nevertheless, a more precise asymptotic development at infinity is suggested by Riemann's results. It is interesting to note that the main purpose of the first letter that S. Ramanujan wrote to G.H. Hardy was to communicate his independent discovery of the asymptotic (see [44])

$$\pi(x) \approx \sum_{n=1}^{+\infty} \frac{\mu(n)}{n} \operatorname{li}\left(x^{\frac{1}{n}}\right),$$

that Ramanujan claimed to be accurate up to the nearest integer, something that numerically is false. His exact words are the following ([25] p.22):

*I have found a function which exactly represents the number of prime numbers less than x , “exactly” in the sense that the difference between the function and the actual number of primes is **generally** 0 or some small finite value even when x becomes infinity... (Letter from Ramanujan to Hardy)*

Hardy, much later, after Ramanujan passed away, made frivolous comments about Ramanujan’s claim, and took good care of explaining why he believed that Ramanujan didn’t seem to know about complex zeros of Riemann’s ζ -function ([25] chapter II). Considering Ramanujan’s success with similar claims, as for instance for the asymptotic of partition numbers (see [43]), one should probably not take the words of Ramanujan so lightly. It is reasonable to conjecture, interpreting his “generally”, that probably Ramanujan’s claim holds for arbitrarily large values of $x \in \mathbb{R}_+$:

Conjecture 2.1. Let $\mathcal{R} \subset \mathbb{R}_+$ be the Ramanujan set of values $x \in \mathbb{R}_+$ for which $\pi(x)$ is the nearest integer to

$$\sum_{n=1}^{+\infty} \frac{\mu(n)}{n} \operatorname{li}\left(x^{\frac{1}{n}}\right),$$

then \mathcal{R} contains arbitrarily large numbers.

In general one may ask how large is the Ramanujan set \mathcal{R} . Does it have full density? That is:

$$\lim_{X \rightarrow +\infty} \frac{|\mathcal{R} \cap [0, X]|}{X} = 1.$$

This does not seem to agree with the plot in [57], but one can expect to have elements of the Ramanujan set in large gaps of primes (large according to how far away is the gap).

3. ON RIEMANN ZETA-FUNCTION AFTER RIEMANN.

A vast amount of work has been done since Riemann’s memoir. It is out of the scope of these notes to give an exhaustive survey. The aim of this section is to describe some results that we consider the most relevant ones that shed some light or might be important to the resolution of the Riemann Hypothesis. In particular, we will not discuss all the numerous equivalent reformulations of the Riemann Hypothesis. Some of these are truly amazing, but unfortunately none of them seem to provide any useful insight into the conjecture.

3.1. Explicit formulas. Riemann’s formula for $\pi(x)$ in terms of the expression involving the non-trivial zeros of ζ is an example of explicit formula for the zeros. It is surprising that despite how little we know about the exact location of the zeros, many such formulas do exist.

Already Riemann stated the formula, for $x > 1$ and $x \neq p^m$,

$$\sum_{n \leq x} \Lambda(n) = x - \sum_{\rho} \frac{x^{\rho}}{\rho} - \frac{\zeta'(0)}{\zeta(0)} - \frac{1}{2} \log(1 - x^{-2}),$$

where the sum over the zeros is understood in the sense

$$\sum_{\rho} \frac{x^{\rho}}{\rho} = \lim_{T \rightarrow +\infty} \sum_{|\Im \rho| \leq T} \frac{x^{\rho}}{\rho} .$$

This formula can be proved applying the integral operator

$$f \mapsto \frac{1}{2\pi} \int_{a-i\infty}^{a+i\infty} f(s) x^s \frac{ds}{s}$$

to formula (2.3).

Another very interesting explicit formula was given by E. Landau ([34] 1911), that shows the very subtle location of the zeros and how they exhibit resonance phenomena at the prime frequencies: When $x > 1$ is a power of p , $x = p^m$, we have,

$$\sum_{0 < \Im \rho < T} x^{\rho} = -\omega_p T + \mathcal{O}(\log T) ,$$

but for $x \neq p^m$ for any prime, we have,

$$\sum_{0 < \Im \rho < T} x^{\rho} = \mathcal{O}(\log T) .$$

Notice that in the first case we have an equivalent which is $\mathcal{O}(T)$ and the terms of the sum do not cancel each other at the same rate as in the second case where the equivalent is $\mathcal{O}(\log T)$. Related to this sum, H. Cramér [11] studied the analytic continuation of the now called Cramér function

$$V(t) = \sum_{\Im \rho > 0} e^{\rho t} .$$

The series is convergent in the upper half plane and despite the singularity at 0 and simple poles at $\mathbb{Z}^* \log p$, Cramér proved its meromorphic continuation. He determined the monodromy at 0 and its poles and residues. A.P. Guinand [22] proved the Guinand's functional equation which is at the source of the meromorphic extension across the real axis:

$$e^{-t/2} V(t) + e^{t/2} V(-t) = e^{t/2} + e^{-t/2} - e^{-t/2} \frac{1}{1 - e^{-2t}} .$$

The general technique to obtain these explicit formulas and results is by computing a contour integral $\int_R \zeta'(s)/\zeta(s) f(s) ds$ over a rectangular contour R , symmetric with respect to the critical line, with horizontal and vertical sides away from the critical strip in two ways: Using the residue theorem (the integrand has simple poles at the non-trivial zeros), and by integrating over the vertical sides, exploiting the symmetry given by the functional equation and the Euler product expansion on the right side (the integral over the horizontal sides is shown to be negligible or tending to 0). This is also the technique used to count the zeros in the critical strip with bounded imaginary part. One can find many of these explicit formulas in the two volume treatise of Landau [33], or in Ingham's book [26].

First A.P. Guinand [21] and then J. Delsarte [13], noticed the Fourier-Poisson duality that transpire from these formulas. For a modern discussion on this aspect and the relation to trace formulas, we refer to P. Cartier and A. Voros enlightening article [7]. Similar to Poisson formula, that can be formulated as a distributional result about the Fourier transform of a Dirac comb, one can give a general distributional formulation, and the application to various test functions yield the different classical *explicit formulas* with the Riemann zeros.

Theorem 3.1. (*Delsarte Explicit Formula*) *In the distribution sense,*

$$2\pi \left(\delta_{i/2} + \delta_{-i/2} + \sum_{\gamma} \delta_{\gamma} \right) = - \sum_{n=1}^{+\infty} \frac{\Lambda(n)}{\sqrt{n}} \left(\hat{\delta}_{\frac{\log n}{2\pi}} + \hat{\delta}_{-\frac{\log n}{2\pi}} \right) - D_{\infty} ,$$

where D_{∞} is the absolutely continuous distribution

$$D_{\infty}(\varphi) = \int_{\mathbb{R}} \varphi(t) \Psi(t) dt ,$$

where

$$\Psi(t) = \log \pi - \frac{1}{2} \frac{\Gamma'(1/2 + it)}{\Gamma(1/2 + it)} - \frac{1}{2} \frac{\Gamma'(1/2 - it)}{\Gamma(1/2 - it)} .$$

In 1952 A. Weil gave a general adelic version of this explicit formula. The form of the distribution corresponding to the infinite place was simplified by K. Barner (see [56] and [35]). Weil observed that the Riemann Hypothesis is equivalent to the positivity of the right hand side of his equation for a suitable class of functions (see [3]). This type of positivity criteria is common to other approaches to the Riemann Hypothesis, as for instance De Branges proposed approach [12].

Explicit formulas have been interpreted as *trace formulas* and conversely. The *trace formula* approach was inaugurated by Selberg's work [48] (1956) on the length spectrum of constant negatively curved compact surfaces (see section 4.9 for the associated zeta-function). It is usually presented as a relation between the Fourier transform of a distribution associated to the length of primitive geodesics, and the eigenvalues of the laplacian. Cartier and Voros gave an interpretation as an explicit formula in [7]. All of this is very much related to the procedure of zeta-regularization that is cherished by physicists ([16], [17]), number theorists ([14]), and first used by geometers ([45]) in order to compute the determinant of the laplacian in a surface with constant negative curvature.

Another geometric interpretation of explicit formulas as a *trace formula* in a non-commutative space was proposed by A. Connes [9]. J.-B. Bost and A. Connes proposed such a space in [4]. Connes reduced the Riemann Hypothesis to the proof of a trace formula. This is very much related to *quantum chaos* (see section 3.3).

3.2. Montgomery phenomenon. In 1972, H. Montgomery [37] studied the distribution of differences of Riemann zeros, and proved, assuming the Riemann Hypothesis plus other assumptions, a weak version of the *Pair Correlation Conjecture*

for the zeros $\rho = 1/2 + i\gamma$. For $T \rightarrow +\infty$,

$$(3.1) \quad \frac{1}{N(T)} \#\left\{(\gamma, \gamma'); 0 < \gamma, \gamma' < T; \gamma \neq \gamma'; \frac{2\pi}{\log T} \alpha < \gamma - \gamma' < \frac{2\pi}{\log T} \beta\right\} \\ \rightarrow \int_{\alpha}^{\beta} \left(1 - \left(\frac{\sin \pi x}{\pi x}\right)^2\right) dx .$$

The claim in the literature is that this statistical behavior gives support to the so called Hilbert-Polya approach to the Riemann Hypothesis: It is enough to show that the Riemann zeros form the spectrum of an Hermitian operator. For the Hilbert-Polya attribution one may consult the correspondence of Odlyzko with Polya in [40]. It seems that E. Landau asked Polya for a physical reason that would explain the Riemann Hypothesis and he came out with his proposal of a physical system whose eigenvalues (energy levels) correspond to the Riemann zeros. As the story tells, F. Dyson recognized the same distribution as for the pair correlation of eigenvalues for the Gaussian Unitary Ensemble (GUE) in Random Matrix Theory used by physicists, which is the set of Hermitian matrices endowed with a gaussian measure.

Extensive computations (O. Bohigas, M. Gianonni [5], and A. Odlyzko [39] [40]) have confirmed the statistics with high accuracy. In particular, A. Odlyzko has pushed the computation of Riemann zeros to various millions and imaginary parts of the order of 10^{20} .

In the personal opinion of the author, it is a bold statement to claim that the GUE statistics (3.1) infers anything about Hilbert-Polya proposal. GUE statistics may just mean that the same Fourier phenomena arises in Random Matrix Theory and other domains. The GUE distribution differs from the constant distribution by the square of a Fresnel or sine-cardinal (non-positive) distribution

$$(3.2) \quad \int_{\alpha}^{\beta} \frac{\sin(\pi x)}{\pi x} dx ,$$

which is just the Fourier transform of a box (or truncation) function. The self-convolution of a box function is a tent function and this is essentially what we can read in the GUE distribution.

In view of the existing literature, it seems to have been unnoticed that the properly normalized error term in (3.1) is asymptotic when $T \rightarrow +\infty$ to a superposition of Fresnel distributions [42], one positive with larger amplitude and the subtraction of an infinite series of lower order ones.

3.3. Quantum chaos. Polya's proposition to Landau to seek for a physical system having the Riemann zeros as energy levels, was pushed forward by M. Berry ([1]) and then by S. Keating ([30], [2]). They assume the Riemann Hypothesis, all the approach is perturbative, and carry out liberally the computations using the divergent Euler product in the critical strip. The purpose is to explore the semiclassical formalism, and how it fits with the classical formulas for the Riemann zeta-function.

The approach consists in considering the imaginary part of the Riemann zeros as energy levels of a semi-classical system and exploit classical perturbative techniques for the quantification of hyperbolic dynamical systems (this explains the term “quantum chaos”). Indeed there is now a well developed theory of quantification of chaotic dynamical systems (see [23]) which was inspired from classical physical techniques (as WKB method). The starting point is the observation that $N(E)$ can be seen as the integrated density of states and Riemann–Von Mangoldt’s formula gives the asymptotic

$$N(E) = \frac{E}{2\pi} \log \left(\frac{E}{2\pi} \right) - \frac{E}{2\pi} + \frac{7}{8} + \frac{1}{\pi} \Im \log \zeta(1/2 + iE) + \mathcal{O}(1) .$$

This expression is composed by the averaged part

$$\langle N(E) \rangle = \frac{E}{2\pi} \log \left(\frac{E}{2\pi} \right) - \frac{E}{2\pi} + \frac{7}{8} ,$$

and the oscillatory term

$$N_{osc}(E) = \frac{1}{\pi} \Im \log \zeta(1/2 + iE) .$$

Plugging in brutally Euler product, replacing $\zeta(1/2 + iE)$, we get

$$N_{osc}(E) = -\frac{1}{\pi} \sum_p \sum_{k \geq 1} \frac{1}{k} e^{-\frac{1}{2} k \log p} \sin(Ek \log p) .$$

The density of states distribution is obtained by differentiating

$$d(E) = dN(E)/dE = \bar{d}(E) - 2 \sum_p \sum_{k \geq 1} \frac{\log p}{2\pi} e^{-\frac{1}{2} k \log p} \cos(Ek \log p) .$$

In the semiclassical approximation of a hamiltonian system one can also give an equivalent when $\hbar \rightarrow 0$ to the density of states and we get an averaged part and an oscillatory part that can be computed using the periodic orbits of the system and its Lyapunov exponents:

$$d(E) = \bar{d}(E) + \frac{2}{\hbar} \sum_p \sum_{k \geq 1} A_{p,k}(E) \cos \left(\frac{k}{\hbar} S_p(E) - k \frac{1}{2} \alpha_p \right) ,$$

where k is number of times the primitive orbit is counted, the phase α_p is the Maslov index around the orbit (monodromy in the symplectic linear group of the linearization along the orbit), and $S_p(E)$ is the action around the orbit

$$S_p(E) = \oint \mathbf{p} \cdot d\mathbf{q} .$$

The amplitudes are given by

$$A_{p,k} = \frac{T_p(E)}{2\pi} e^{-\frac{1}{2} \lambda_p(E) k T_p(E)} ,$$

where $T_p(E)$ is the period of the primitive orbit, and λ_p is the sum of Lyapunov exponents (trace of the linear part of the Poincaré return map).

This allows to infer some information about the hypothetical Polya hamiltonian system. The periods of the primitive orbits would be the logarithms of primes $T_p = \log p$, $\alpha_p = 0$ and $\lambda_p = 1$. Unfortunately, there are also notable differences, the most important one the divergent sign of the oscillatory part. But these computations have proved useful and serve as a guide to infer results, as for example the prediction of n -point correlations between Riemann zeros.

The amazing analogy means one of two things: Either there is really a Polya physical system behind Riemann zeta function, or both theories share a good deal of common formalism. Since nobody has been able to have a good guess for such a Polya system, and in view of some of the mismatching, we are inclined to favor the second possibility.

3.4. Adelic character. Euler product formula and its relation to prime numbers shows that the Riemann zeta function has a deep algebraic meaning. The reasons to believe in the Riemann Hypothesis are not only analytic. All the rich generalizations of the conjecture to other transcendental zeta functions do arise for zeta functions with a marked arithmetic character, more precisely with a well defined Euler product exhibiting local factors. This is probably where the real difficulty lies: The truth of the conjecture must depend on a mixture of analytic and arithmetic ingredients.

We have seen that the Euler product expansion naturally suggests the “local” factors corresponding to each prime number,

$$\zeta_p(s) = (1 - p^{-s})^{-1} .$$

But the functional equation naturally introduces a more natural entire function ξ which contains a new factor

$$\frac{1}{2} s(1-s)\pi^{-s/2}\Gamma(s/2) .$$

How it should be interpreted? Tate in his thesis (1950, [50] [8]) provides a uniform explanation to the new factor as the one corresponding to the infinite prime, and unifies the treatment of functional equations for various zeta and L functions. Tate’s approach is based on doing Fourier analysis at each local completion of \mathbb{Q} (or of a number field K , but we limit the exposition to \mathbb{Q} in this section). We recall Ostrowski’s theorem [41] which classifies all absolute values over Ψ up to topological equivalence.

Theorem 3.2. (A. Ostrowski) *Up to topological equivalence, all absolute values over the rational numbers are the ultrametric p -adic absolute value $|\cdot|_p$ and the archimedean absolute value $|\cdot|_\infty$.*

As usual, we note by \mathbb{Q}_p the completion of \mathbb{Q} for the p -adic absolute value $|\cdot|_p$. The corresponding completion for $|\cdot|_\infty$ is \mathbb{R} . Tate does Fourier analysis on the *idèle* group

$$\mathbb{A}^\times = \prod'_p \mathbb{Q}_p^\times ,$$

where the restricted product means that only a finite number of coordinates are not in \mathbb{Z}_p^\times . We have an embedding $\mathbb{Q}^\times \hookrightarrow \mathbb{A}^\times$, and a decomposition

$$\mathbb{A}^\times \approx \mathbb{Q}^\times \times \mathbb{R}_+^\times \times \hat{\mathbb{Z}}^\times ,$$

where

$$(3.3) \quad \hat{\mathbb{Z}}^\times = \varprojlim_n (\mathbb{Z}/n\mathbb{Z})^\times \approx \prod_p \hat{\mathbb{Z}}_p^\times .$$

A quasi-character or Hecke character is a continuous complex character $\omega : \mathbb{A}^\times \rightarrow \mathbb{C}^\times$ which is trivial on \mathbb{Q}^\times . These decompose into local characters $\omega = \otimes_v \omega_v$ and in each local completion \mathbb{Q}_v for $f_v \in \mathcal{S}(\mathbb{Q}_v)$ (the appropriate Schwartz class) we can define the Fourier-Mellin local transform

$$Z_v(s, \omega_v, f_v) = \int_{\mathbb{Q}_v^\times} f_v(x) \omega_v(x) |x|_v^s d_v^\times x ,$$

where $d_v^\times x$ is the multiplicative Haar measure normalized so that for v_p, \mathbb{Z}_p^\times has volume 1. We have also a global Fourier-Mellin transform in the *idèles* for $f \in \mathcal{S}(\mathbb{A})$

$$Z(s, \omega, f) = \int_{\mathbb{A}^*} f(x) \omega(x) |x|^s d^\times x ,$$

and

$$Z(s, \omega, f) = \prod_v Z_v(s, \omega_v, f_v) .$$

These transforms do have a meromorphic extension to all $s \in \mathbb{C}$ and Fourier duality gives for them a functional equation for the substitution $s \mapsto 1 - s$. From the complement factors we get the usual zeta function and its local parts (see [50] or [32] for details). The explicit computation is

$$\xi_p(s) = \int_{\mathbb{Q}_p^\times} \mathbf{1}_{\mathbb{Z}_p}(x) |x|_p^s d^\times x = (1 - p^{-s})^{-1} = \zeta_p(s) .$$

where $d^\times x = \frac{1}{1-p^{-1}} \frac{dx}{|x|_p}$. And for $p = \infty$, $d^\times x = \frac{dx}{|x|}$ and $\mathbf{1}_{\mathbb{Z}_p}$ is replaced by a Gaussian (the natural replacement would be by δ_0 , the Dirac at 0, that is a limit of gaussians):

$$\xi_\infty(s) = \int_{\mathbb{R}} e^{-\pi x^2} |x|^s \frac{dx}{|x|} = \pi^{-\frac{s}{2}} \Gamma\left(\frac{s}{2}\right) .$$

The functions ξ_p are the *local factors* of ζ . For $p = \infty$ is the real or infinite prime (this classical terminology should be replaced by “the prime $p = 1$ ” as the Cramér function tells us clearly), ξ_∞ is called the *local archimedean factor*. Then we reconstruct the global zeta-function as

$$\xi(s) = \frac{1}{2} s(s-1) \xi_\infty(s) \prod_p \xi_p(s)$$

The necessity of introducing a factor at infinity to obtain the functional equation is better understood in view of the analogy between number and function fields (see

section 4.4). As a matter of fact, $\text{Spec } \mathbb{Z}$ is similar to the affine line $\mathbb{A}_k^1 = \text{Spec } k[T]$. The *product formula* links together all different valuations

$$|x|_\infty \prod_p |x|_p = 1 \quad \forall x \in \mathbb{Q}^*$$

and this makes natural the simultaneous consideration on the same footing of all of them, and the hypothetical compactification $\overline{\text{Spec } \mathbb{Z}}$. This is the point of view of Arakelov geometry.

It remains to interpret the factor $s(s-1)$. An exotic interpretation was proposed by Y. Manin in [36]: It would be the zeta-function of the projective line over the *field with one element*.

4. THE UNIVERSE OF ZETA-FUNCTIONS.

In order to better understand the true scope of the Riemann Hypothesis, we need to put it in context in the vast universe of zeta functions. These arise naturally in different fields of Mathematics, always with a rich associated structure. Many times they encode deep arithmetical information. They provide bridges and unsuspected analogies between distinct fields that have proved to be the key points in the proof of central conjectures. The rich structure of such universe of zeta-functions is not well understood. Many mysterious relations and analogies appear with no easy explanation:

It's a whole beautiful subject and the Riemann zeta function is just the first one of these, but it's just the tip of the iceberg. They are just the most amazing objects, these L-functions -the fact that they exist, and have these incredible properties are tied up with all these arithmetical things- and it's just a beautiful subject. Discovering these things is like discovering a gemstone or something. You are amazed that this thing exists, has these properties and can do this. (J.B. Conrey)

It is very likely that a proof of the Riemann Hypothesis for Riemann zeta-function entails the unveiling of this hidden structure as a biproduct, and the proof is expected to work in a much larger class of zeta-functions.

We start by the simplest and closer generalizations of Riemann zeta-function, and then we grow in generality and complexity. As we climb levels into increasing generality we notice a diminishing knowledge of analytic properties.

4.1. Dirichlet L-functions. To any given Dirichlet character we can associate a Dirichlet L-function in the following way. Let $\chi : \mathbb{Z} \rightarrow \mathbb{C}^*$ be a Dirichlet character defined modulo $q \geq 1$, that is, a q -periodic lift of a group morphism $(\mathbb{Z}/q\mathbb{Z})^\times \rightarrow \mathbb{C}^*$ such that $\chi(n) = 0$ when $(n, q) \neq 1$. Thus we have the multiplicative property $\chi(nm) = \chi(n)\chi(m)$ and $|\chi(n)| = 1$ when $\chi(n) \neq 0$. The character is *primitive* when it is not induced by another character modulo $q'|q$. The *conductor* is the minimal of such q 's. We define for $\Re s > 1$,

$$L(s, \chi) = \sum_{n=1}^{+\infty} \frac{\chi(n)}{n^s} = \prod_p (1 - \chi(p)p^{-s})^{-1} .$$

The multiplicative property of χ is what yields the Euler product. For $q = 1$, $\chi = 1$, we recover Riemann zeta-function, and for $q \geq 2$ and if the character is primitive and non-trivial ($\chi \neq 1$), then $L(s, \chi)$ extends as an entire function over \mathbb{C} , thus has no poles.

These L -functions do satisfy a functional equation with symmetry respect to $\Re s = 1/2$ when χ is a real valued character, or quadratic character, $\chi = \bar{\chi}$. Note that this case corresponds to have $L(s, \chi)$ real analytic. In general the functional equation only relates $L(s, \chi)$ and $L(s, \bar{\chi})$. If χ is a primitive character with conductor q (we can reduce to this case modulo a finite number of Euler factors), then we have again a complement factor involving a Γ factor satisfying the **DL** property. If

$$\Lambda(s, \chi) = \pi^{-\frac{s+a_\chi}{2}} \Gamma\left(\frac{s+a_\chi}{2}\right) L(s, \chi)$$

where $a_\chi = 0$ or $a_\chi = 1$ depending whether $\chi(-1) = 1$ (even character) or $\chi(-1) = -1$ (odd character). We denote by $\tau(\chi)$ its Gauss sum,

$$\tau(\chi) = \sum_{x=0}^{q-1} \chi(x) e^{\frac{2\pi i}{q} \cdot x} ,$$

and we define the *root number* as $\epsilon(\chi) = q^{-1/2} \tau(\chi)$ for χ even, and $\epsilon(\chi) = -iq^{-1/2} \tau(\chi)$ for χ odd, then $|\epsilon(\chi)| = 1$. Then we have

$$\Lambda(\chi, s) = \epsilon(\chi) q^{1/2-s} \Lambda(1-s, \bar{\chi}) .$$

When χ is a quadratic character, we have $\epsilon(\chi) = 1$.

These L -functions were used by Dirichlet in his proof that in any arithmetic sequence of integers $(a+nq)_{n \in \mathbb{Z}}$, $(a, q) = 1$, there are infinitely many primes, mimicking Euler's analytic proof of the existence of an infinite number of prime numbers. The result is equivalent to prove that when χ is non-trivial, then $L(1, \chi) \neq 0$. Thus we find here another example where the location of zeros has a deep arithmetical meaning.

At this point, since for a general Dirichlet L -function we have no self-functional equation, we may wonder if the same intuition that has led to formulate the Riemann hypothesis does makes sense for a non-quadratic character L -function. Observing that $Z(s, \chi) = L(s, \chi) \cdot L(s, \bar{\chi})$ does indeed satisfy a self-functional equation, that it is a function in the **DL** class, with an Euler product, and that its divisor is just the union of both divisors, it is clear that again we can formulate the Riemann Hypothesis, that is indeed equivalent to the Riemann Hypothesis for both factors.

Generalized Riemann Hypothesis. All non-real zeros of $L(s, \chi)$ lie on the vertical line $\Re s = 1/2$.

4.2. Dedekind zeta-function. Dedekind's zeta-function is associated to a number field K of degree $d = [K : \mathbb{Q}]$. The ring of integers \mathcal{O}_K is a Dedekind ring

where we have unique factorization of integer ideals by prime ideals. Dedekind's zeta-function is defined for $\Re s > 1$ by

$$\zeta_K(s) = \sum_{\mathfrak{a} \subset \mathcal{O}_K} \frac{1}{N(\mathfrak{a})^s} = \prod_{\mathfrak{p} \subset \mathcal{O}_K} (1 - N(\mathfrak{p})^{-s})^{-1},$$

where \mathfrak{a} runs over all ideals of the ring of integers, and \mathfrak{p} over all prime ideals. For $K = \mathbb{Q}$ we recover Riemann zeta-function $\zeta = \zeta_{\mathbb{Q}}$.

If K is a Dedekind domain, every ideal has a unique factorization as a product of prime ideals, so

$$\zeta_K(s) = \prod_{\mathfrak{p} \subset \mathcal{O}_K} (1 - N(\mathfrak{p})^{-s})^{-1}.$$

Hecke proved the meromorphic extension to \mathbb{C} with a simple pole at $s = 1$, and the functional equation. If we write

$$\Lambda_K(s) = \pi^{r_1 s/2} (2\pi)^{r_2 s} \Gamma(s/2)^{r_1} \Gamma(s/2)^{r_2} \zeta_K(s),$$

where r_1 and r_2 are the number of real and complex embeddings $K \hookrightarrow \mathbb{C}$, then if D is the *discriminant* of K ,

$$\Lambda_K(s) = |D|^{1/2-s} \Lambda_K(1-s).$$

Dedekind zeta-function ζ_K encodes in itself important arithmetic information. The best example is the analytic class number formula, that shows that we can read in the residue of ζ_K at $s = 1$ important arithmetic information:

$$\operatorname{Res}_{s=1} \zeta_K(s) = \frac{2^{r_1} (2\pi)^{r_2} h(K) R}{w \sqrt{D}},$$

where w is the number of roots of unity in K , R is the regulator, and $h(K)$ the class number of K . The extension of this idea is what leads to Birch and Swinnerton-Dyer conjecture for L -functions of elliptic curves that is the subject of the exposition by V. Rotger in this same volume [47].

The Riemann Hypothesis is also conjectured in the same form for Dedekind zeta-functions.

This construction was later generalized by Hecke (1917) with the introduction à la Dirichlet of characters in the ideal class group, and later (1918, 1920) with the introduction of “Größencharakter” which is a character in the *idèle* class group. For these zeta and L -functions, Tate approach unifies the treatment of the local factors, meromorphic extension and functional equation.

4.3. Artin L -functions. With Artin L -functions we jump another ladder in conceptual generality and we start losing important analytic information. The reason is that Artin L -functions are defined through their Euler product, something that makes very difficult to prove meromorphic extension without an alternative analytic expression.

Any Dirichlet primitive character of conductor q is a character χ_{Gal} on the group $\operatorname{Gal}(\mathbb{Q}(e^{2\pi i/q})/\mathbb{Q}) \approx (\mathbb{Z}/q\mathbb{Z})^\times$ (and hence on the profinite group $\operatorname{Gal}(\bar{\mathbb{Q}}/\mathbb{Q})$), such that $\chi(p) = \chi_{\text{Gal}}(\sigma_p)$, where σ_p is the element of the Galois group given by

the Frobenius automorphism $x \mapsto x^p$. Moreover any 1-dimensional character on $\text{Gal}(\bar{\mathbb{Q}}/\mathbb{Q})$ is of this form. We can write the Dirichlet L -function as

$$(4.1) \quad L(s, \chi) = \prod_p (1 - \chi_{\text{Gal}}(\sigma_p) p^{-s})^{-1} .$$

Now, given a finite dimensional linear representation of an abstract group G , $\rho : G \rightarrow GL(V)$, its character is given by

$$\chi(g) = \text{Tr} \rho(g) .$$

We consider the situation where K is a finite extension of a number field k (of even a function field), and $\rho : G \rightarrow GL(V)$ a representation of the Galois group $G = \text{Gal}(K/k)$ into the finite dimensional linear vector space V , and χ its character. For each prime ideal \mathfrak{p} in K , the Frobenius automorphism $\sigma_{\mathfrak{p}}$ acts on $V^{I_{\mathfrak{p}}}$, where $I_{\mathfrak{p}}$ is the inertia group of \mathfrak{p} in G ($V^{I_{\mathfrak{p}}} = V$ when \mathfrak{p} does not ramify). Then the local Artin L -function is defined by the characteristic polynomial of this action:

$$(4.2) \quad L_p(s, \chi) = \text{Det} (1 - N(\mathfrak{p})^{-s} \sigma_{\mathfrak{p}} | V^{I_{\mathfrak{p}}})^{-1} ,$$

and then the global Artin L -function for finite places is given by the product of the local factors

$$(4.3) \quad L(s, \chi) = \prod_p L_p(s, \chi) .$$

Note that the local factors here are no longer linear functions on p^{-s} , but are polynomial functions. In order to complete the picture, one introduces the archimedean factor that is a combination of

$$\begin{aligned} \Gamma_{\mathbb{R}}(s) &= \pi^{-s/2} \Gamma(s/2) \\ \Gamma_{\mathbb{C}}(s) &= \Gamma_{\mathbb{R}}(s) \Gamma_{\mathbb{R}}(s+1) , \end{aligned}$$

in order to get $\Lambda(s, \chi)$.

With these definitions it is difficult to prove any meaningful analytic result, starting from the meromorphic extension. The only success is obtained when, by algebraic means, one could identify the L -function with others for which a more analytic (not from Euler's product) definition is at hand. The meromorphic extension, and the functional equation are indeed proved in two steps. First for the case of a one-dimensional representation: Class Field theory shows that $L(s, \chi)$ is a Hecke L -function, hence we get meromorphic extension, and the functional equation. Second, using a fundamental theorem of R. Bauer (1947) on the classification of characters on a finite group, the general case is reduced to one-dimensional representations. We get an expression in terms of Dedekind zeta-functions. We get a functional equation of the form:

$$\Lambda(1-s, \chi) = W(\chi) \Lambda(s, \chi) ,$$

where $W(\chi) \in \mathbb{C}$, the *Artin root number*, is of modulus 1.

Again the Riemann Hypothesis is conjectured, and in this case follows from the Riemann Hypothesis for Dedekind zeta-functions. A. Weil generalized both Artin and Hecke zeta-functions by introducing Grössencharakteren in the construction.

4.4. Zeta-functions of algebraic varieties. The well-known analogy between number fields and function fields first started by Dedekind and Weber fundamental article (R. Dedekind and H. Weber, *Theorie der Algebraischen Functionen einer Veränderlichen*, J. de Crelle **92**, 1882, 181–290), has always been a source of inspiration and testing. In general hard results for the number field case have been tested and proved to be more accessible in the function field case. This also happens in the theory of zeta and L -functions.

Along the lines of Dedekind's definition in the Number Field case, H. Kornblum used zeta-functions of algebraic varieties over a finite field to prove an analog of Dirichlet theorem on primes on arithmetic progressions. Later E. Artin continued this work and defined these zeta-functions in a more general context and studied the Riemann Hypothesis. Then Hasse and Schmidt proved the analogue of the Riemann Hypothesis for elliptic curves, and Weil finally proved it for general curves. We define now zeta-functions for algebraic varieties over a number field K , or over a finite field $K = \mathbb{F}_q$, $q = p^k$. We start by the finite field case $K = \mathbb{F}_p$. The algebraic extensions of \mathbb{F}_p are the \mathbb{F}_{p^k} for $k = 1, 2, 3, \dots$ which are characterized dynamically as the set of periodic points of period k of the Frobenius automorphism $x \mapsto x^p$. Let X_p be an algebraic variety defined over \mathbb{F}_p of dimension n . We define N_k to be the number of points of X_p in the field extension \mathbb{F}_{p^k} , and

$$Z(t, X_p) = \exp \left(\sum_{k=1}^{+\infty} N_k \frac{t^k}{k} \right),$$

or $\zeta(s, X_p) = Z(p^{-s}, X_p)$ in the more familiar $s \in \mathbb{C}$ variable. Note that in this case, from the definition, the function $\zeta(s, X_p)$ is $i\omega_p^{-1}\mathbb{Z}$ periodic as the familiar local ζ_p factor. It is clear that this defines an analytic function in a right half plane.

Example: For $X = \mathbb{P}^1$, $Z(t, \mathbb{P}^1) = (1-t)^{-1}(1-pt)^{-1}$.

In 1949, inspired by his work on curves, Weil proposed a set of conjectures for these zeta-functions for n -dimensional algebraic varieties. The conjectures for curves were proposed in 1924 by Artin.

- **Rationality.** The zeta-function $Z(t, X_p)$ is a rational function of $t \in \mathbb{C}$, i.e. $\zeta(s, X_p)$ is a rational function of p^{-s} .
- **Functional equation.** We have $Z(\frac{1}{p^n t}, X_p) = \pm p^{nE/2} t^E Z(t, X_p)$, where E is the self-intersection of the diagonal in $X_p \times X_p$.
- **Riemann Hypothesis.** We do have

$$Z(t, X_p) = \frac{P_1(t)P_3(t)\dots P_{2n-1}(t)}{P_0(t)P_2(t)\dots P_{2n}(t)},$$

where $P_0(t) = 1 - t$, $P_{2n}(t) = 1 - p^n t$ and for $1 \leq j \leq 2n - 1$, $P_j(t) = \prod_{k=1}^{B_j} (1 - \alpha_{jk} t)$ where the α_{jk} are algebraic integers and $|\alpha_{jk}| = p^{\frac{j}{2}}$.

- **Betti numbers.** When X_p is the reduction of a complete non-singular algebraic variety in characteristic 0, then the degree B_j of P_j is the j -th Betti number of X as a complex manifold.

It is interesting to note that in this case, using the periodicity in $s \in \mathbb{C}$, just the functional equation (second conjecture) plus the meromorphic extension to \mathbb{C} implies the rationality conjecture. Also the third conjecture is really a **DL** property with $2n$ vertical lines, which shows again that the **DL** property arises naturally in this new context.

In 1934 Hasse proved these results for elliptic curves and in 1940 Weil solved them for curves of arbitrary genus. In 1960 B. Dwork, proved the rationality. Then M. Artin, A. Grothendieck, J.-L. Verdier and others developed l -adic étale cohomology theory. This gave the polynomials P_j à la Artin from the action of the Frobenius automorphism on cohomology. The functional equation then followed from Poincaré duality, and the degrees B_j were identified as Betti numbers. Finally, in 1974 P. Deligne proved the Riemann Hypothesis using the available technology of Lefschetz pencils and a positivity argument by Rankin in the theory of modular zeta-functions which is the key estimate, and that was obtained in this setting by a clever geometrical argument from an algebraic index theorem. As a corollary, Deligne obtained a good estimate for the coefficients of modular functions associated to elliptic curves, in particular settling Ramanujan conjecture for the original modular function. The original goal of Rankin was precisely to obtain better estimates on the coefficients of modular functions. More precisely, Ramanujan τ -function $\tau(n)$ is given by the modular form, which generates a modular zeta-function (as explained in section 4.6) that is also the zeta function of an algebraic curve,

$$\sum_{n \geq 1} \tau(n)q^n = q \prod_{n \geq 1} (1 - q^n)^{24} = \eta(\tau)^{24} ,$$

where η is Dedekind η -function. Ramanujan conjecture claims that for p prime we have

$$\tau(p) \leq 2p^{11/2} .$$

Now we discuss the case where X is a non-singular algebraic variety defined over a number field, or just over \mathbb{Q} in order to simplify. For almost every prime, except for the so called “bad reduction primes”, the reduction X_p of X modulo p is a non-singular algebraic variety X_p over \mathbb{F}_p . We define the Hasse-Weil zeta function by the product (we avoid the finite number of primes for which X_p may not be defined),

$$Z_{X, \mathbb{Q}}(s) = \prod_p' Z_p(p^{-s}, X_p) .$$

Note that **the zeta functions of X over \mathbb{F}_p do appear as Euler local factors.** We should stress this point because we do have now a genuine transcendental function, and not a rational function as before. The mixture of rationally independent frequencies (ω_p) clearly shows that we are no longer facing a vertically periodic function of the $s \in \mathbb{C}$ variable.

Hasse conjecture postulates the existence of a meromorphic extension. For the functional equation and the Riemann Hypothesis conjecture, one has to take into account the precise form of the Euler local factors (Serre, 1969), and usually is preferable to work separately with the zeta functions that are supposed to satisfy a minimal **DL** property (with only one vertical line for the location of the vertical divisor),

$$\zeta_j(s, X) = \prod_p' P_j(p^{-s}, X_p)^{-1} .$$

Examples:

(1) **Projective space \mathbb{P}^1 .** For $X = \mathbb{P}^1$, $\zeta_0(s, \mathbb{P}^1) = \prod_p (1 - p^{-s})^{-1} = \zeta(s)$ and we recover the usual Riemann zeta-function. Also $\zeta_2(s, \mathbb{P}^1) = \prod_p (1 - pp^{-s})^{-1} = \zeta(s - 1)$, and

$$Z_{X, \mathbb{P}^1}(s) = \prod_p (1 - p^{-s})^{-1} (1 - pp^{-s})^{-1} = \zeta(s) \zeta(s - 1) .$$

(2) **Elliptic curves.** We refer to the text of V. Rotger in this same volume [47] for examples and a detailed discussion. We just mention that the key point in the resolution of Fermat's problem is the proof of the Taniyama-Weil conjecture. This conjecture postulates the modularity of the zeta-function of elliptic curves, i.e. that these L -function come also from modular forms in the sense of section 4.6, and this yields many previously unknown analytic properties. This is a very good example of the kind of bridges between distinct parts of the zeta-function universe that provides an insight in many problems.

Comments.

At this point it should be clear that the zeta-functions of varieties over finite fields represent nothing more than local Euler factors of the Hasse-Weil transcendental zeta-functions. Despite the difficulties and technicalities involved in the proof of the Riemann Hypothesis for these local zeta functions, coming back to the discussion in the first section, the result is equivalent in this context to Euler's proof that the sine function has no complex zeros, i.e. that the local factor $\zeta_p(s)$ satisfies the Riemann Hypothesis. How can this result represent a significant advance towards the Riemann Hypothesis? In no way in the author's opinion. The knowledge of the Riemann Hypothesis for $\zeta_p(s)$ has not provided yet any clue about how to go about the transcendental aspects of the Riemann Hypothesis for the transcendental zeta function $\zeta(s)$. One may agree with E. Bombieri's claim [3] that

“Deligne's theorem surely ranks as one of the crowning achievements of 20th century mathematics.” (E. Bombieri)

because of the important techniques and inspiring arguments used in the proof, but there is no reason to claim that this represents a significant advance towards the Riemann Hypothesis for transcendental zeta-functions. The Riemann Hypothesis for rational zeta functions (rational in the appropriate variable, or periodic in

s), are “toy zeta-functions” where one can test the Conjecture, and the algebraic arguments, but they cannot give any clue about the intrinsic transcendental difficulty attached to the problem. It is natural that pure algebraists may downsize or overlook these difficulties. But one should be very careful in how things are presented and what claims are made in order to get the correct intuition on the real problem.

It is interesting to note that another example of “toy zeta-functions” is provided by dynamical zeta-functions associated to hyperbolic dynamical systems (see section 4.8). As we will see in section 4.8, it is possible to encode the dynamics with a finite Markov partition, which provides a combinatorial encoding of periodic orbits, and a combinatorial framework that is used to prove the rationality of the zeta-function. This result is of the same nature as Deligne’s result.

4.5. L -functions of automorphic cuspidal representations. Inspired by the adelic ideas of Tate, in the seventies there was a development for a general theory of a very large class of L -functions associated to automorphic cuspidal representations of $GL(n, \mathbb{A})$ where \mathbb{A} is the adèle group of \mathbb{Q} , that are supposed to generalize all previous zeta and L -functions. Such a representation π is equivalent to $\otimes_v \pi_v$ where π_v is an irreducible unitary of $GL(n, \mathbb{Q}_v)$. We will give a sketchy presentation because of lack of space in order to introduce all the terminology.

When v_p is a finite prime, one determines from π_p a local factor $L(s, \pi_p)$ which is a polynomial on p^{-s} of degree n . Then the associated L -function is

$$L(s, \pi) = \prod_p L(s, \pi_p) .$$

For $v = \infty$, then π_∞ determines n parameters $(\mu_{j, \pi_\infty})_{1 \leq j \leq n}$ and

$$L(s, \pi_\infty) = \prod_{j=1}^n \Gamma(s - \mu_{j, \pi_\infty}) .$$

Then the function

$$\Lambda(s, \pi) = L(s, \pi_\infty) \cdot L(s, \pi) ,$$

satisfies the functional equation

$$\Lambda(s, \pi) = \epsilon_\pi N_\pi^{1/2-s} \Lambda(s, \tilde{\pi}) ,$$

where $|\epsilon_\pi| = 1$, $N_\pi \geq 1$ is an integer, and $\tilde{\pi}$ is the contragredient representation.

A general conjecture of Langlands is that these L -functions generate multiplicatively all previous L -functions (Dirichlet, Dedekind, Hecke, Artin, Hasse-Weil,...). And we expect the Riemann Hypothesis to hold in this class of L -functions:

Grand Riemann Hypothesis. The zeros of $\Lambda(s, \pi)$ all have real part $1/2$.

Again, as for Artin L -functions, one of the weak points of the general definition of L -functions associated to automorphic representations is that the definition by the Euler product is analytically unusable. It is necessary already from the very definition to prove that the L -function has a meromorphic extension to \mathbb{C} .

4.6. Classical modular L -functions. We recall that Riemann gave an integral formula expressing Riemann ζ -function from the classical θ -function, and the functional equation for ζ resulted from the modular functional equation for θ . This procedure generalizes to give a large family of zeta-functions associated to certain modular forms. These form the class of modular L -functions that have good analytic properties. This time we are taking a different path and are not escalating in generality.

Let $\mathbb{H} = \{z \in \mathbb{C} : \Im z > 0\}$ be the upper half plane and let H be a subgroup of $\mathrm{SL}(2, \mathbb{Z})$ containing a congruence subgroup

$$\Gamma(N) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \equiv \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} [N] \right\}$$

Definition 4.1. A *meromorphic modular form* of weight k relative to H is a meromorphic function $f : \mathbb{H} \rightarrow \overline{\mathbb{C}}$ such that

$$f\left(\frac{az+b}{cz+d}\right) = (cz+d)^k f(z) \text{ for all matrices } \begin{pmatrix} a & b \\ c & d \end{pmatrix} \text{ in } H,$$

and f is meromorphic at the cusps, that is, when H acts on f , the resulting function has a meromorphic expansion in $q^{1/N}$ at $q = 0$ for the variable $q = e^{2\pi iz}$, that is

$$(cz+d)^k f\left(\frac{az+b}{cz+d}\right) = \sum_{n=-r}^{+\infty} a_n q^{n/N}.$$

We say that f is a *modular form*, resp. *parabolic modular form*, when it is holomorphic at the cusps (always $r \leq 0$), resp. vanishes at the cusps ($r \leq -1$).

In order to simplify, we limit the discussion to $N = 1$. Let M_k , resp. S_k , be the vector spaces of modular, resp. modular parabolic, forms for $H = \mathrm{PSL}(2, \mathbb{Z})$. The space M_k is finite dimensional and its dimension can be computed explicitly. We have $\dim M_k = [k/12]$ if $k \equiv 2[12]$, and $\dim M_k = [k/12] + 1$ otherwise. Moreover we have,

$$M_k = S_k \oplus \mathbb{C}G_k,$$

where G_k is the Eisenstein series.

From f and more precisely, its expansion at infinity, we construct an L -function by

$$L(f, s) = \sum_{n=1}^{+\infty} \frac{a_n}{n^s}.$$

In order to have good properties for this L -functions (Euler product, functional equation,...) we need to restrict our class of modular forms to those with good arithmetic properties. The selection is done taking eigenfunctions of the Hecke operators.

For $n \geq 1$, we define the Hecke operator $T_n : M_k \rightarrow M_k$ or $T_n : S_k \rightarrow S_k$ by

$$T_n f(\tau) = n^{k-1} \sum (c\tau + d)^{-k} f\left(\frac{a\tau + b}{c\tau + d}\right),$$

where the sum runs over the matrices $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \text{PSL}(2, \mathbb{Z})/\mathcal{M}_n$ where \mathcal{M}_n is the set of integral matrices of order two having determinant n .

Since

$$T_n T_m = \sum_{d|(n,m)} d^{k-1} T_{\frac{nm}{d^2}} ,$$

when n and m are coprimes, $T_n T_m = T_m T_n$. Then T_n and T_m diagonalize in the same bases. A Hecke form is an eigenvector $f \in S_k$ for all T_n . If $f(z) = \sum_{n=1}^{+\infty} a_n q^n$, then $a_1 \neq 0$, so it can be normalized to $a_1 = 1$. The coefficients are algebraic numbers $a_n \in \overline{\mathbb{Q}}$ with degree bounded by the dimension of S_k . Moreover we have the multiplicative relations for the a_n :

$$a_n a_m = \sum_{d|(n,m)} d^{k-1} a_{\frac{nm}{d^2}} .$$

One can find a bases of Hecke forms for M_k . Now if f is a Hecke form, the associated L -function has an Euler product that comes from the multiplicative relations for the (a_n) :

$$L(s, f) = \sum_{n=1}^{+\infty} \frac{a_n}{n^s} = \prod_p (1 - a_p p^{-s} + p^{k-1} p^{-2s})^{-1} .$$

Then $L(s, f)$ converges for $\Re s > k$, and for $\Re s > \frac{k}{2} + 1$ when f is a cuspidal form. One can prove the meromorphic extension to all of \mathbb{C} . It is an holomorphic function for f cuspidal and has a simple pole at $s = k$ otherwise. We have the functional equation:

$$(2\pi)^{-s} \Gamma(s) L(s, f) = (-1)^{\frac{k}{2}} (2\pi)^{s-k} \Gamma(k-s) L(k-s, f) .$$

4.7. L -functions for $GL(n, \mathbb{R})$. A vast generalization of the precedent modular L -functions was started by H. Maass in 1949 when he noticed that we don't really need classical modular forms in order to generate L -functions, but non-holomorphic automorphic forms are enough.

More precisely, one looks for eigenfunctions of the Laplace operator for the Poincaré metric in the upper half plane which is invariant by the action of $SL(2, \mathbb{Z})$:

$$\Delta = -y^2 \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) .$$

The function $I_s(z) = y^s$ is an eigenfunction with eigenvalue $s(1-s)$, and averaging over the action of $SL(2, \mathbb{Z})$ we do get the Eisenstein series:

$$E(z, s) = \frac{1}{2} \sum_{c, d \in \mathbb{Z}; (c,d)=1} \frac{y^s}{|cz + d|^s} .$$

Its Fourier expansion can be computed:

$$E(z, s) = y^s + \varphi(s) y^{1-s} + \frac{2\pi^s \sqrt{y}}{\Gamma(s)\zeta(2s)} \sum_{n \in \mathbb{Z}^*} \sigma_{1-2s}(n) |n|^{s-1/2} K_{s-1/2}(2\pi|n|y) e^{2\pi i n x} ,$$

where

$$\varphi(s) = \sqrt{\pi} \frac{\Gamma(s - 1/2)}{\Gamma(s)} \frac{\zeta(2s - 1)}{\zeta(2s)} ,$$

$$\sigma_s(n) = \sum_{d|n} d^s ,$$

and K_s is the Bessel function

$$K_s(y) = \frac{1}{2} \int_0^{+\infty} e^{\frac{1}{2}y(u+1/u)} u^s \frac{du}{u} .$$

Thus we see that from these Fourier coefficients we can construct the L -function associated to the Eisenstein series

$$L_{E(\cdot, w)}(s) = \sum_{n \geq 1} \sigma_{1-2w}(n) n^{w-1/2-s} = \zeta(s + w - 1/2) \cdot \zeta(s - w + 1/2) .$$

This motivates to look for a general definition for Maass forms:

Definition 4.2. Let $L^2(\mathbb{H})$ be the space of square integrable functions with respect to the Poincaré volume. A Maass form is $f \in L^2(\mathbb{H})$ such that

- $\forall \gamma \in SL(2, \mathbb{Z})$, we have $f(\gamma \cdot z) = f(z)$.
- $\Delta f = \nu(1 - \nu)f$.
- $\int_0^1 f(z) dz = 0$.

If f is a mass form, then it has a Fourier expansion of the form

$$f(z) = \sum_{n \in \mathbb{Z}^*} a(n) \sqrt{2\pi y} K_{\nu-1/2}(2\pi|n|y) e^{2\pi i n x} .$$

We can define commuting Hecke operators $(T_n)_{n \geq 1}$ commuting with the Laplacian and acting on the space of mass forms. If f is a mass form normalized with $a(1) = 1$ and being the eigenvalue of all Hecke operators, then for $n = 1, 2, 3, \dots$

$$T_n(f) = a(n)f ,$$

and the (a_n) do satisfy multiplicative relations. If f is odd or even and we define the associated L -function by

$$L_f(s) = \sum_{n=1}^{+\infty} a(n) n^{-s} ,$$

the multiplicative relations give the Euler product:

$$L_f(s) = \prod_p (1 - a(p)p^{-s} + p^{-2s})^{-1} .$$

One can show that these L -functions have a holomorphic continuation to all of \mathbb{C} and satisfy the following functional equation:

$$\Lambda_f(s) = (-1)^\epsilon \Lambda_f(1 - s) ,$$

where

$$\Lambda_f(s) = \pi^{-s} \Gamma\left(\frac{s + \epsilon - 1/2 + \nu}{2}\right) + \Gamma\left(\frac{s + \epsilon + 1/2 - \nu}{2}\right) L_f(s) ,$$

where $\epsilon = 0$ if f is even, and $\epsilon = 1$ if f is odd.

Through the Iwasawa decomposition in $GL(n, \mathbb{R})$ we can define a generalization of the upper half plane \mathbb{H} ,

$$\mathbb{H}_n = GL(n, \mathbb{R}) / (O(n, \mathbb{R}) \cdot \mathbb{R}^*) ,$$

and we can consider the algebra of $SL(n, \mathbb{Z})$ invariant differential operators, Hecke operators and the corresponding Maass for $SL(n, \mathbb{Z})$. Then through their Fourier coefficients, R. Godement and H. Jacquet defined their associated L -functions that have an Euler product whose local factors are polynomials of degree n in p^{-s} . The Rankin-Selberg convolution operator can be defined, and has better analytic properties in the $GL(2, \mathbb{R})$ theory than in the higher dimensional $GL(n, \mathbb{R})$ theory where it is more formally defined.

This vast generalization led to R.P. Langlands to a set of conjectures known as “The Langlands Program”.

4.8. Dynamical zeta-functions. Zeta-functions encode in a wonderful way arithmetical information. They can also encode dynamical and geometrical information as we see now.

Following the path of the definitions of zeta-functions over algebraic varieties, where we noted the role played by the dynamics of the Frobenius map, we can define in a similar way the zeta-function of a dynamical system (f, X) , $f : X \rightarrow X$. For $j = 1, 2, 3, \dots$, let $N_j(f)$ be the number of fixed points of the j -th iterate f^j , that is the number of distinct solutions to $f^j(x) = x$ (we will assume that this number is finite). Then the zeta-function associated to f is

$$Z_f(t) = \exp \left(\sum_{j=1}^{+\infty} \frac{N_j(f)}{j} t^j \right) .$$

If the number of fixed points grow at most in an exponential way, this defines a holomorphic function in a neighborhood of $t = 0$.

Fundamental example: Subshift of finite type.

We consider the dynamics of a shift of finite type. We denote $\Sigma(l) = \{1, 2, \dots, l\}^{\mathbb{Z}}$ the compact space endowed with the product topology. An element $x \in \Sigma(l)$ is a sequence of the l symbols of the alphabet, $x = (x_j)_{j \in \mathbb{Z}}$. The space is metrisable and a Cantor set. The shift homeomorphism is the map $\sigma : \Sigma(l) \rightarrow \Sigma(l)$ defined by

$$\sigma(x)_j = x_{j+1} .$$

Let $A = [a_{ij}] \in M_{l \times l}(\{0, 1\})$ be a square $l \times l$ matrix of zeros and ones. We can associate to A the compact subspace

$$\Sigma_A = \{x \in \Sigma(l); \forall j \in \mathbb{Z}, a_{x_j x_{j+1}} = 1\} .$$

The shift σ leaves Σ_A invariant. The subshift of finite type associated to A is the dynamical system (σ_A, Σ_A) with $\sigma_A : \Sigma_A \rightarrow \Sigma_A$ where $\sigma_A = \sigma|_{\Sigma_A}$ is the restriction of the shift.

This type of systems arise often in dynamics when we want to code a dynamical system. If $(X_j)_{1 \leq j \leq l}$ is a partition of X (Markov partition), and $f : X \rightarrow X$

is an invertible dynamical system on X , we can associate a transition matrix A by defining $a_{ij} = 1$, if $f(X_i) \cap X_j \neq \emptyset$, or $a_{ij} = 0$ otherwise. Then we can encode the orbit of any $x \in X$ by associating to x the sequence of symbols $\varphi(x)$ with

$$f^j(x) \in X_{\varphi(x)_j} .$$

When the dynamical system is not invertible, we can consider only the lateral shift, or we can also construct an invertible dynamical system taking an inverse limit by a classical construction.

We can combinatorially enumerate the number of periodic orbits of the subshift of finite type in a very simple way:

Lemma 4.3. *For $n \geq 0$, we have*

$$N_n(\sigma_A) = \text{Tr} A^n .$$

From this we get that the associated zeta-function is rational:

$$Z_{\sigma_A}(t) = \exp \left(\sum_{j=1}^{+\infty} \frac{\text{Tr} A^j}{j} t^j \right) = (\text{Det}(I - tA))^{-1} .$$

There are some systems that do have a good coding and for which we can prove the rationality of the zeta-function in full generality. These are the hyperbolic dynamical systems (see [49]). For example, the linear map given by the matrix $\begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$ on the two dimensional torus \mathbb{T}^2 is hyperbolic. Such systems are stable under perturbations. A more general notion is of Axiom A diffeomorphism $f : M \rightarrow M$ of a compact manifold M , which means the non-wandering set $\Omega(f)$ of f is hyperbolic and periodic orbits are dense on it. Then we can construct a Markov partition of $\Omega(f)$ with rectangular regions delimited by pieces of stable and unstable manifolds, using the existing local product structure: for two nearby points $x, y \in \Omega(f)$, we can grow a small local stable manifold from x , $W_\epsilon^S(x)$, and a small local unstable manifold from y , $W_\epsilon^U(y)$, such that they intersect in a single point $[x, y] = W_\epsilon^S(x) \cap W_\epsilon^U(y) \in \Omega(f)$. Except for the orbits hitting the common boundaries, the orbit is uniquely determined by its coding. Thus, in such a way we can count the periodic orbits, except for the redundancy on the orbits going through boundaries of the Markov partition. This allows to prove, by pure combinatorial enumeration, that the zeta function is rational.

It may seem surprising that for example an hyperbolic diffeomorphism of the torus \mathbb{T}^2 has such a rational function, considering that rationality should come from an algebraic phenomena. The mystery disappears when one learns that such an arbitrary diffeomorphism is always topologically equivalent to a linear map, and the count of periodic orbits is clearly the same for both systems.

We have discussed dynamical zeta-functions for discrete iteration. We can also define zeta-functions for continuous dynamical systems (flows) by measuring (with a natural or auxiliary Riemannian metric) the length of periodic orbits. For example, Selberg zeta-function for the geodesic flow of a compact surface of constant

negative curvature is of this nature. Selberg zeta function encodes the length spectrum, i.e. the set of length of primitive simple geodesics.

4.9. The Selberg class. In 1992 A. Selberg proposed the more general class of zeta-functions for which he expected the Riemann Hypothesis to hold.

The Selberg class \mathcal{S} is composed by those Dirichlet series¹

$$F(s) = \sum_{n=1}^{+\infty} a_n n^{-s} ,$$

that are absolutely convergent for $\Re s > 1$ that satisfy the following four conditions:

- **Analyticity.** There is $m \geq 0$ such that $(s-1)^m F(s)$ is an entire function.
- **Ramanujan Conjecture.** $a_1 = 1$ and $a_n = o(n^\epsilon)$ for any $\epsilon > 0$.
- **Functional equation.** There is a factor of the form

$$\gamma_F(s) = \epsilon Q^s \prod_{j=1}^k \Gamma(w_j s + \mu_j) ,$$

where $|\epsilon| = 1$, $Q > 0$, $w_j > 0$, $\Re \mu_j \geq 0$ such that

$$\lambda(s) = \gamma_F(s) F(s) ,$$

satisfies the functional equation

$$(4.4) \quad \Lambda(s) = \overline{\Lambda(1-\bar{s})} .$$

- **Euler Product.** We have for $\Re s > 1$

$$F(s) = \prod_p F_p(s) ,$$

and

$$\log F_p(s) = \sum_{k=1}^{+\infty} b_k p^{-ks} ,$$

and for some $\theta \in]0, 1/2[$, we have $b_{p^k} = \mathcal{O}(p^{k\theta})$.

On top of the Riemann Hypothesis, Selberg made a set of conjectures for this class of Dirichlet series known by the name of *Selberg Conjectures*.

4.10. Kubota-Leopold zeta-function. These zeta and L -functions are of a very different nature than the previous examples. This time, the generalization goes into a different direction: these are zeta-functions of a p -adic variable.

The starting point is the observation of the remarkable rational values given by Bernoulli numbers, taken by $\zeta(s)$ at the negative integers, for $n \geq 1$,

$$\zeta(1-n) = -\frac{B_n}{n} \in \mathbb{Q} .$$

Let $p \neq 2$ (for $p = 2$ the formulas change) be a prime number and fix $u \in \mathbb{Z}/(p-1)\mathbb{Z}$. When $n_k \rightarrow s$ in $\mathbb{Z}/(p-1)\mathbb{Z} \times \mathbb{Z}_p$, as $k \rightarrow +\infty$, with the restriction $n_k \equiv u \pmod{p-1}$, one can prove (using Kummer congruences for Bernoulli numbers) that

¹There is a much larger class of functions that are not Dirichlet series for which to expect the Riemann hypothesis.

the sequence $(\zeta(1 - n_k))_k$ is converging in the p -adic field \mathbb{Q}_p . Indeed there exists an analytic function in \mathbb{Q}_p defined by

$$\zeta_{p,u}(s) = \lim_{k \rightarrow +\infty} \zeta(1 - n_k)(1 - p^{n_k}) ,$$

which interpolates the values taken by $\zeta(s)(1 - p^s)$ at the $s = 1 - n_k$. For u even we get $\zeta_{p,u} = 0$.

We have the formulas, for odd u and $n \leq 0$, $n \equiv u[p - 1]$

$$\zeta_{p,u}(n) = (1 - p^{-n})\zeta(n) ,$$

and for $n \geq 1$, $n \equiv u[p - 1]$,

$$\zeta_{p,u}(n) = \frac{\Gamma(n)}{(2\pi i)^n} (1 - p^{n-1})\zeta(n) .$$

We should note that $u + (p - 1)\mathbb{N}$ and $u - (p - 1)\mathbb{N}$ are dense in \mathbb{Z}_p .

5. CONCLUSION AND COMMENTS ON THE RIEMANN HYPOTHESIS.

5.1. Is it true? The first question one has to ask about an open conjecture is if we do actually believe it. In the case of the Riemann Hypothesis there seems to be an overwhelming opinion in favor of it. And this, despite that the vast majority of mathematicians that have an opinion don't have a clue on how to go about it. Also despite some notable exceptions of unbelievers. Indeed, it appears that some of the best specialists that have spend considerable effort into it, at the end of their life start to become skeptic. We can just mention the best known of them, J.E. Littlewood. At first this seems quite troubling. But knowing human nature, probably we can only take this as another indication that the Riemann Hypothesis is certainly true. One can notice that most (all?) of the attempts to resolve the questions have tried to prove and not disprove it. The only attempts to disprove it seem to have been numerical. We will not even discuss the possibility of the Riemann Hypothesis to be non-decidable: It is obviously a genuine well posed beautiful problem.

The arguments in favor of the Riemann Hypothesis that one finds in the literature are weak.

- **Numerical evidence.** As some authors have observed, the range at the scope of present computer power is probably not large enough to draw any conclusion in view that ranges where $\log \log T$ is large should be inspected (see [28]).
- **Proportion of zeros in the critical line.** Goes into the right direction, but says nothing about the totality of zeros.
- **Weak density of zeros away from the critical line.** Same comment as before.
- **True for toy models.** As the zeta function of algebraic varieties over finite fields, or hyperbolic Dynamical Systems. Obviously these go into the right direction, but miss the central analytic difficulty for transcendental functions. This explain why these results are tractable by purely

geometric-algebraic, or combinatorial methods, but the transcendental problem seems totally out of reach.

- **Spectral Hilbert-Polya approach.** It is certainly a very appealing proposition, but does not give direct support unless we have a proposition for the unitary operator that will have the non-trivial zeros as spectrum. The dream of finding a physical hamiltonian-like system with this spectrum of energies is very unlikely to succeed. In view of the universe of zeta-functions, the system for Riemann zeta-function would be a very basic and almost canonical one. Thus easy to find. So far, no such system has been proposed. It is very likely that it does not exist. Most probably the part of the hidden structure of the universe of zeta-functions is shared by mechanical systems, which would explain the observed analogies.

5.2. **Why is it hard?** As most of the thought problems, it is hard because it contains in a non-trivial way a mixture of analytic and arithmetic elements. One can probably argue the same way for two other problems exposed in this volume: The Hodge conjecture, and the Birch and Swinnerton-Dyer conjecture. The conjecture will not succumb to only analytic nor algebraic methods. It would be necessarily a combination.

The analytic subtlety consists in the influence of the Eulerian expansion away from its half plane of convergence. This is a matter touching the theory of re-summation that involves a certain amount of complex analysis magic and fine analytic theory. The arithmetic subtlety is contained in the \mathbb{Q} -independence of the prime frequencies (ω_p) . By this we mean that a light perturbation of the prime frequencies in the Euler product,

$$\zeta(s) = \prod_p \left(1 - e^{-\frac{\omega_p}{2\pi} s}\right)^{-1},$$

even assuming the subsistence of a meromorphic extension, will very likely destroy the Riemann Hypothesis (cf. Beurling zeta function). It is very hard to fully exploit this simple fact in a subtle analytical argument. There is no need to say that there is no approach so far that exploits both facts in full. There has not been any genuine analytic-algebraic attack. History shows a long list of failures and partial results, hard to improve, which are genuinely purely analytic or purely algebraic... and all of them very far from the goal.

Reviewing the analytic progress towards the Riemann Hypothesis is quite frustrating. The pathetic attempts to enlarge the ridiculous zero free region in the critical strip is a perfect example of what brute force can do without fully exploiting fundamental arithmetic aspects of the problem. And we can go on and on, with such examples, where the goal is becoming more and more on improving the epsilons, which evidences the fact that the gap towards the conjectured results will never be filled by such methods without some very original input.

Reviewing the algebraic progress towards the Riemann Hypothesis is equally frustrating. Only the toy models for non-transcendental functions have been dealt with. Pushing such methods to transcendental zeta functions has been tried and

seems well out of scope. The Grothendieckian approach to divinize and solve with a trivial corollary, does not seem well adapted to the analytic nature of the problem (indeed to any hard concrete analytic problem). The rich structure of the universe of zeta-functions, allows to combinatorially construct L -functions with a complete lack of analytic information. This explains the proliferation of interrelated conjectures that after all is just another evidence that some analytic results are missed.

One may bet that the real hard problem is the Riemann Hypothesis for Riemann zeta-function, and all the vast other generalizations would fall from the techniques, in a pretty similar way, or with some extra not so hard technique.

All of this is masterly summarized in the following quotation, that every researcher in the field should read with humility:

There have probably been very few attempts at proving the Riemann hypothesis, because, simply, no one has ever had any really good idea for how to go about it. (A. Selberg)

5.3. Why is it important? As Gauss would put it: Mathematics is the queen of Sciences, Number Theory is the queen of Mathematics, and the theory of prime numbers is the queen of Number Theory. To unveil the fundamental structure of central theories is what marks the progress of Science.

But to solve the Riemann Hypothesis is central for many other reasons. It will vindicate, once more, the aesthetic intuition in Mathematics. Also from a practical point of view, it will prove at once all the numerous conditional results that exist.

It is one of the actual principal challenges of Mathematics. These challenges, as the quadrature of the circle, the resolution of algebraic equations, Euclid's fifth postulate, ... are the only objective measure of progress in Mathematics.

Also, the resolution of the Riemann Hypothesis will very likely unlock the hidden structure in the universe of zeta-functions. This will open vast new fields of research.

And last, but not least, so much effort has been put on it, that the solution will save thousands of hours of mathematical research.

It is worth to note that the Riemann Hypothesis is the only Millennium Problem that was on Hilbert's list of open problem. Let's see what Hilbert and others had to say:

...it still remains to prove the correctness of an exceedingly important statement of Riemann: that the zero points of the function $\zeta(s)$ all have the real part $1/2$, except the well-known negative integral real zeros. (D. Hilbert, Description from the 8th Hilbert problem)

The failure of the Riemann Hypothesis would create havoc in the distribution of prime numbers. This fact alone singles out the Riemann Hypothesis as the main open question of prime number theory. (E. Bombieri)

The Riemann Hypothesis is the central problem and it implies many, many things. One thing that makes it rather unusual in mathematics today is that there must be over five hundred papers -somebody should go and count- which start “Assume the Riemann Hypothesis,...” and the conclusion is fantastic. And those “conclusions” would then become theorems . . . With this one solution you would have proven five hundred theorems or more at once. (P. Sarnak)

5.4. Ingredients in the proof. From the contemplation of the panorama of zeta-functions, failed attempts and various results, one can guess some of the ingredients that the proof should contain. Intuition and experience tell us that it is very unlikely that two very distinct proofs may exist. There is almost a uniqueness parathorem about uniqueness of proofs for results combining far away branches of mathematics.

It is not very hard to guess some elements that are very likely to be present in the final proof.

- The vast universe of zeta and L -functions reveals an enormous hidden structure that must be unveiled. This analytic-algebraic structure is very likely to provide the key for the resolution of the Riemann Hypothesis. Also, this extra structure would explain the appearance of different L -functions in very different contexts: Simply there is not enough place in one complex variable to admit more than one of such algebra of functions.
- A pairing with some sort of positivity argument is very likely to be part of the key point in the argument. Not only Deligne’s proof for his toy model incorporates it, but various proposed approaches (A. Weil, L. De Branges, physical approach...) also rely on this. The positivity may only yield a weaker result, as for example the non-existence of a finite number of zeros outside the critical line. For the full conjecture, more probably other ingredients will be needed.
- A technique that allows the Euler product in the critical strip seems unavoidable. For example, a proxy for the Euler product that has a global meaning.
- Heavy Fourier analysis mixed with complex variable must be used in a non-trivial form that incorporates in full the basic arithmetic aspects.

5.5. Receipts for failure. This text grew up from lectures addressed to a broad and young mathematical audience. It may be important to give them some warnings. Most of these observations apply to most of the hard open problems that exist in Mathematics.

- **Don’t expect simple proofs to ever work.** It would be very naive to think otherwise.
- **Don’t work on it unless you have very novel and powerful ideas.** Many of the best Mathematicians of all times have failed. Something more than existing techniques and tools are needed. You need a really good idea

and striking new tools. Most of what you believe that is a good or novel idea, it is not. We hope that this text will help you to decide that.

- **Don't work on it without a clear goal.** As mentioned, you must first decide if you believe the conjecture or not. There is no point in trying to prove the conjecture one day and trying to disprove it the next day. A clear goal is a source of strength that is needed.
- **Don't expect that the problem consists in resolving a single hard difficulty.** In this kind of hard problems many enemies are on your way, well hidden, and awaiting for you.
- **Don't work on it without studying previous attempts.** We know by now of several failed attempts, and you should learn them in order to not repeat history again.
- **Don't go for it unless you have succeed in other serious problems.** "Serious problems" mean problems that have been open and well known for years. Before setting goals, you better check that they are realistic. Picasso didn't start his career with the Guernica. If you think that the Riemann Hypothesis will be your first major strike, you probably deserve failure.
- **Don't tell anyone out of your closer circle that you work on the problem.** Or you will be put aside on the freak category and will put unwanted pressure on you.
- **Do tell and discuss with your very best mathematical friends your work on the problem.** You will need to check very carefully the progress you make.
- **Don't get obsessed nor make your main goal of it.** Unless you want to ruin your mathematical career.
- **Don't work on it for a monetary reward.** If you want to earn a million dollar and more, there are much simpler ways, eg. find a nice trick in finance and trading. Moreover you should know that the dollar is doomed...

Once having checked on this list... there is only one thing to say: Good luck!

6. APPENDIX. EULER'S Γ -FUNCTION.

For a complex number s in the half plane $\Re s > 0$, we define

$$\Gamma(s) = \int_0^{+\infty} e^{-x} x^s \frac{dx}{x} .$$

Then $\Gamma(1) = 1$ and by integration by parts $\Gamma(s + 1) = s\Gamma(s)$. In particular, $\Gamma(n) = (n - 1)!$ for every $n \in \mathbb{N}$, so the gamma function interpolates the factorial. The function Γ can also be defined for all $s \in \mathbb{C}$ as the limit

$$\Gamma(s) = \lim_{n \rightarrow \infty} \frac{n^s n!}{s(s+1) \cdots (s+n)} .$$

This shows that Γ is always a non-zero function with simple poles at 0 and the negative integers such that $\text{Res}_{s=-n} \Gamma(s) = \frac{(-1)^n}{n!}$.

We have that $1/\Gamma(s)$ is an entire function having $-\mathbb{N}$ as divisor. Thus the order of $1/\Gamma(s)$ is 1. We have then the Weierstrass factorization

$$\frac{1}{\Gamma(s)} = se^{\gamma s} \prod_{n=1}^{+\infty} \left(1 + \frac{s}{n}\right) e^{-\frac{s}{n}}.$$

We have the complement formula

$$\Gamma(s)\Gamma(1-s) = \frac{\pi}{\sin \pi z},$$

observing that both sides of the equation have the same divisor, order 1, and same equivalent for $s \rightarrow 1$.

In particular, the evaluation at $s = 1/2$ gives $\Gamma(1/2) = \sqrt{\pi}$.

Legendre duplication formula can be obtained again by checking that both sides also have the same divisor, order 1 and comparing asymptotic when $s \rightarrow 1$,

$$\Gamma\left(\frac{s}{2}\right) \Gamma\left(\frac{s+1}{2}\right) = 2^{1-s} \sqrt{\pi} \Gamma(s).$$

And finally, we have *Gauss formula*

$$\Gamma\left(\frac{s}{n}\right) \Gamma\left(\frac{s+1}{n}\right) \cdots \Gamma\left(\frac{s+n-1}{n}\right) = n^{\frac{1}{2}-s} (2\pi)^{\frac{n-1}{2}} \Gamma(s).$$
